Course 1: Applied Zoology and Lab Work

Course code: ZO (N) 121 and ZO (N) 121L

Credit: 3+1

Unit number	Block and Unit title	Page number
	Block 1 Applied Zoology	
1	Aquaculture : General principles of aquaculture: Induced breeding, Composite Fish culture, layout of fish farm and management and by-products of fishing Industry, prawn culture and pearl culture	1-26
2	Sericulture: Different kinds of silk producing insects. Host plants of silk Insects. Rearing and diseases of silkworm, reeling and fiber technology	27-42
3	Apiculture: Honey bees of india. Management of bee colonies, bee Enemies and their control. Extraction and processing of honey. Role of honey b pollination.	43-59
4	Lac culture: Different kinds of lac producing insects. Host plants, life cycle and diseases of lac insects.	60-69
5	Poultry: Types of poultry breeds, poultry housing, farm and farm Management. Grading, handling and marketing of eggs, poultry diseases And their control.	70-99
6	Economic importance of mammals: Economic importance of mammals in Agriculture, horticulture, dairy, leather, wool, and fur industry	100-139
7	Store grain pests: Pulse beetle (<i>Callosobruchus maculatus</i>), Rice weevil (<i>Sitophilus oryzae</i>), Wheat weevil (<i>Trogoderma granarium</i>), rust red flour beetle (<i>Tribolium castaneum</i>) and lesser grain borer (<i>Rhizopertha dominica</i>). Their systematic positions, habits, life cycle, nature of damage and control measures.	140-163
8	Pest management: Biological and chemical control: Elementary knowledge of pesticides and integrated pest management	164-183
9	Parasitology: General character and classification up to order level, Morphology (including adaptations), life cycle, pathogenicity, disease Caused and control measures of Entamoeba, Trypanosoma, Leishmania, Giardia, Ascaris, Ancylostoma, Enterobius, Wuchereria and Schistosoma.	184-247
10	Cold water aquaculture and its scope in uttarakhand: Objective, introduction, scope of aquaculture for sustainable livelihood, aquaculture	248-271

	Of cold water fishes, polyculture of carps, sewage feed fisheries, summary, terminal questions and answers	
	Applied Zoology Lab Work {ZO (N) 121 L}	
1	Specimen/ slides of Apis, Silk moth, Lac insect Phytoparasitic nematodes, major carps and store grain pests Pictures of economically important varieties of poultry and cattle Parasites/ slides Entamoeba, Trypanosoma, Leishmania, Giardia, Enterobius, Wuchereria and Schistosoma Economic importance of Apiculture, Sericulture, Lac culture and poultry chart/model	272-310

UNIT- 1 AQUACULTURE

CONTENTS

1.1- Objectives

1.2-Introduction

1.3 General principles of aquaculture

1.3.1 Induced breeding

1.3.2 Composite fish culture

1.3.3 Layout of fish farm and its management & its Management

And the by-product of fishing Industry

1.4 Prawn Culture

1.5 Pearl Culture

1.6-Terminal question

1.7-References

.

1.1 OBJECTIVES

The main objectives of aquaculture are:

- To boost economy of the nation by way of increasing per production.
- To generate employment opportunities for the unemployed persons.
- To utilize fully the natural water resources available to the maximum.
- To uplift the socio-economic status of the people of Indian sub-continent.
- To earn foreign exchange revenue by transport of fish to foreign countries.
- To culture ornamental fishes for beautifying aquariums.
- To culture larvicidal fishes for control of mosquito larvae.
- To increase production of food, in the form of fish, and decreasing the pressure on other food items.

1.2 INTRODUCTION

The term 'Aquaculture' means culture of all aquatic forms like fish, prawns, molluscs and sea weeds in fresh, brackish as well as marine waters. The 'Aquaculture' includes the type of culture systems utilized, e.g., pond culture, cage culture, pen culture, etc. The type of organisms cultured e.g., fish, oyster, shrimp or prawns etc. The origin of aquaculture dates back to at least three thousand years ago, but unlike agriculture, which has been the most important way of obtaining food on land, aquaculture has until recently contributed very less to mankind due to age old methods in use coupled with lack of proper knowledge. But now the picture is changing rapidly as aquaculture is gaining more importance in the today's modern world, due to increase in population and shortage of food.

1.3 GENERAL PRINCIPLES OF AQUACULTURE

The evidence about fish culture practised in India years ago came from the 'kautilya's 'Arthshastra' in which he mentioned about the secret means of keeping fish in reservoirs. 'King Someshwara' of Chanakya Dynasty described the methods of fattening the fish in ponds.

There is a long period regarding fish culture in India until, collection and transportation of carp spawn, from rivers and stocking the ponds, was developed traditionally in Bengals,

Bihar and Orissa by the end of 19th century. This technique spread in other states also and a notable advance in fish culture in Bengal was the construction of 'Bundhs' for carp breeding. Warm water fish culture got a boost when under the guidance of 'H.C. Wilson' the first big fish farm with facilities of carp breeding came into existence in Tamil Nadu (TN).

The Indian Council of Agriculture Research (ICAR) recommended sponsoring fisheries research schemes by State Governments and Universities on different aspects of fish culture. For extending fish culture activities to all parts of the country Govt. Of India established the Central inland fisheries Research Institute (CIFR) at Barrackpore (west Bengal). The pond culture substation of CIFRI was started at Cuttack (Orissa) in 1949 for finding solutions to problems of fish culture in ponds and thereafter a considerable thrust has been laid on research programmes in inland fisheries.

Development after 1970 has led to the use of 'Second generation Techniques' including mammalian hormones, steroids, prostaglandin, and its analogues to make the cultivated species spawn for seed production.

The central institute of Fisheries Education (CIFE) Versova, Mumbai, Aquaculture Research and Training Centre, Kakinana, Central Marine Fisheries Research Institute (CMFRI), Cochin; Central Institute of Freshwater Aquaculture (CIFA), Kausalyganganga, Orissa, Central Institute of Brackishwater Aquaculture, Chennai, have been established for the development of aquaculture in India.

(a) Trout Propagation: History

The trout originated in France and the monk Don Pinchot of 14th century discovered the artificial propagation of trout eggs. Being a sport fish the, trout culture spread to almost all continents thereafter. Commercial trout culture developed in countries like France, Denmark, and Japan and recently in Norway and Italy. With the development of 'Cage farming' of Trout in Norwegian 'firods' salmonoid culture achieved a remarkable place in production and public attention.

The fish culture in North America was cantered earlier towards propagation of salmon and trout. In 18th century trout hatcheries were established. Gradually the trout propagation spread to the temperature and semi temperate areas of central and South America. The

British introduced trout in Asia and Africa, mainly to develop sport fisheries. The first attempt to transplant trout in India was made at Nilgiris in Western Ghats of Tamil Nadu.

(b) Exotic Fish culture in India and other countries

Besides trouts there are other species which from their place of origin have been introduced in other countries for culture purpose, e.g. *Cyprinus carpio* is the most extensively cultivated species worldwide. In India, the common carp (*Cyprinus carpio*) is cultured in combination with Indian major carps.

The silver carp (*Hypophthalmichthys molitrix*,) has been introduced in many countries and cultured in China, Taiwan, Thailand, Malaysia, Japan, Sri Lanka, India, Pakistan, Nepal, Philippines, Russia, Myanmar, Hong Kong, Singapore and Israel. In India for the first time fingerlings of silver carp were brought from Japan in 1959. Likewise, the Grass Carp (from China) and *Tilapia mossambica* (from Africa) have been transplanted throughout the world for cultural practices. There was resistance to its introduction in many countries as it was considered a pest by some countries. The larvivorous fishes were also introduced in different parts of the world.

The catfish family Clariidae enjoys the widest range of geographical distribution and species *Clarias gariepinus* (Nile catfish) from Africa was introduced in South Vietnam in 1974. From Vietnam it reached Campuchia, Laos and Thailand and it and gets entry in India, in 1993.

(c) Coastal Aquaculture

The oldest form of 'Coastal Aquaculture' is the 'Oyster Farming' practised by the early Romans, Greeks and Japanese. In Japan around 2000 years ago coastal aquaculture was practised. Aristotle mentioned the cultivation of Oysters in Greece. The culture of mussels and clams developed at a quite later stage. The terms 'mariculture' and 'sea Farming' are frequently used for raising organisms in the marine environment until recently, and from the worldwide interest, that the sea framing has received in recent years, it appears that sea will be cultivated on a large-scale. The animals now cultured include shrimps, lobsters, oysters and clams.

(d) Sea weed Culture: Sea weed culture is relatively of recent origin. The earliest reference about 'sea weed' culture appears to have published in Japan in 1952. It was after 2nd world war the culture of edible sea weeds expanded and intensified considerably and practised in Korea, Taiwan and China. In Philippines and Hawaii several species of algae are regularly eaten. Most of the species of sea weeds contain 'Gelatin', used for the preparation of Jelly

and Jams. Dried sea weeds are regularly used in domestic cookery for making soups, pudding etc. The active ingredient in the sea weeds is 'Agar' (Sodium Alginate) which is used as a gelling substance.

Aquaculture in India

India is the second largest producer with about 9% share of the world's total aquaculture. The top producer is China (57%).

Freshwater Aquaculture in India:-

Inland aquaculture emerged today, as a major fish producing system in India (Fig 5.1) with production around 1.7 million ton/yr. Carp accounts for over 80% of cultured fish. Major carps cultured are Rohu (*Labeo rohita*), Catla (*Catla catla*) Mrigal (*Cirrhinus mrigala*), Grass carp (*Ctenopharyngodon idellus*), Common carp (*Cyprinus carpio*), silver carp (*Hypophthalmichthys molitrix*), Magur (*Clarias batrachus*), singhi (*Heteropneustes fossilis*) Rainbow trout (*Salmo gairdneri*) and giant prawn (*Macrobrachium rosenbergii*).

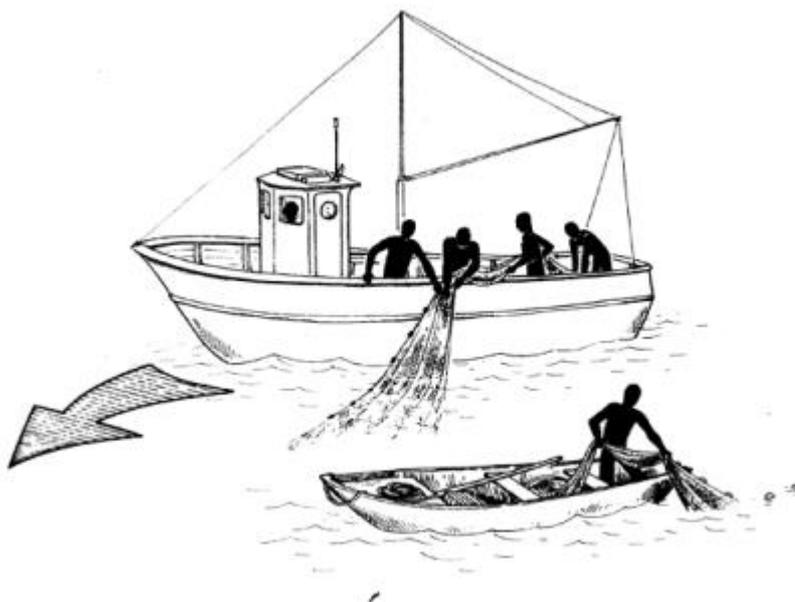

Fig.1.1 catching of fish

West Bengal is the largest producer of fish in India. The state is also the largest supplier of fish seed and supplies nearly 80% of the carp seed demand of the country.

The Central Institute of Freshwater Aquaculture (CIFA) Kausalyaganga (Orissa) established in 1986 is the top level institute in the country with the motto of conducting research on different aspects of freshwater aquaculture and undertaking transfer of technology to the field. The institute serves as the lead centre on carp farming.

Brackish water Aquaculture in India:-

The area of brackish water available in India for aquaculture is 1.19 million ha. Traditional shrimp farming practices are popular in Kerala, West Bengal, and Goa. The yields vary from 300 to 1000 kg/ha/year. Because of its high commercial value, Giant tiger prawn (*Penaeus monodon*) is the dominant species in commercial production; although, Indian white prawn (*Penaeus indicus*) is also farmed in several places. Shrimp production by farming reached a record value in 1994-95. Subsequently production suffered a setback due to a ban imposed by the Supreme Court of India in response to petition filed by environmentalists pleading that shrimp farming had created severe environmental damages. Subsequently many shrimp farms in coastal areas were closed. Intensive shrimp farming is banned and only modified improved farming is permitted with a productivity of around 2 to 2.5 ton/ha/yr. West Bengal is the highest producer of shrimps in India. Its estuarine area in the Sunderbans is ideally suited for the extensive culture of prawns and shrimps.

Marineculture (Sea Farming) in India:-

Indian 'Sea farming' progress has been very slow. Of the 1.2 million ha. of potential land identified for shrimp farming only about 100,000 ha. is utilized. The slow progress in this area is due to the collapse of the shrimp farming industry because of environmental concerns and disease problems. Although the present attention is towards diversification of fish species other than shrimp the commercial ventures are constrained due to unreliable seed supply and lack of technology for commercial marine finfish hatchery seed production. The culture of sea bass (*Lateolabrax sp.*), milkfish (*Chanos chanos*), grey mullets (*Mugil sp.*), pearl spot (*Etroplus sp.*) etc. has been practiced in India since 1960's.

Fig.1.2 *Chanos chanos* (Milk fish)

1.3.1 INDUCED BREEDING

The artificial process by means of which the extract of the pituitary is introduced inside the body of both the matured male and female fishes, then the carps after being excited lay eggs in the pond water and subsequently fertilization takes place and the process is called **induced breeding** of fishes. This process of breeding is also known as **hypophysation**.

1. Collection of pituitary extract:

From the matured fishes of both sexes either belonging the same species as the recipient or a closely related the pituitary glands are collected. It is preferred to collect the pituitary gland from freshly killed fishes. But it has been observed that the pituitary glands taken from five to eight days old ice-preserved fishes have also given successful results. In the fish markets, where the head of the cut fishes are available the pituitary glands can be taken out from the posterior end of the cranium through the foramen magnum after cleaning the brain tissue.

2. Preparation of pituitary extract:

For the induced breeding of fishes the preparation of pituitary extract is very important. It is very easy to prepare. Immediate after the collection the pituitary glands are kept in absolute alcohol for dehydration. After 24 hours, the alcohol is changed for further dehydration and defatting. The glands are then weighed and preserve in fresh alcohol in dark colored phials. It may be stored at room temperature or in a refrigerator. The weight of each pituitary gland varies from 7 to 19 mg in Rohu weighing 1kg to 3.8 kg and 3 to 23 mg in Mrigal weighing 0.3 to 3.6 kg. At the time of injection to carps for the induced breeding, the required quantity of pituitary glands are taken out of the phials and the alcohol is allowed to evaporate. The glands are then macerated with a tissue homogenizer either in distilled water or 0.3 percent of saline water. The gland suspension is then centrifuged and the supernatant fluid is drawn into a hypodermic syringe for the injection.

3. Method of injection and spawning:

During the rainy season, the extract of the pituitary gland of the same species which is prepared on the above said scientific process is injected in the muscle of the matured carps, 1.5 kg the 5.5 kg weight in general. Just before evening, per one female with two males of the approximate same body weight are to be injected the pituitary extract by hypodermic syringe. Injection of the carps is to be done outside of the water lying on a piece of sponge which is

used only to avoid the injury of the carps. In case of male carps the pituitary extracts are introduced once and in case of female carps it is introduced twice.

Then the carps, i.e., one female and two male are placed in a breeding hapa for spawning. Inside of the breeding hapa both the female and male carps are excited. After the excitation the female carps lays eggs. The eggs are externally fertilized by the spermatozoa that are discharged by the males. After that all the fishes are removed from the breeding hapa and then the eggs are collected by a net and are transferred to the inner part of the hatching hapa. After 14 to 18 hours, the spawns enter into the outer hapa and the induced breeding process completed. Then the spawns are collected from the outer hapa and transferred to the pond for nursery.

Advantages of induced breeding:-

- i) Eggs and spawns of carps collected from the river bed, there are possibility of mixture of other fish eggs and spawns. Whereas, in the induced breeding there is no possibility of mixture and as a result the pure form of fish seeds are obtained.
- ii) Desired species of carps can be cultured through the induced breeding.
- iii) Large numbers of eggs are available from a fish through induced breeding.
- iv) In the same season, a carp can be induced to breed more than once.
- v) Transportation cost becomes very low as the carps can be breed in any desired pond.
- vi) Between the different species of fishes hybridization can be done and it is possible to get hybrid variety of fishes.

1.3.2 COMPOSITE FISH CULTURE

Fish is the cheapest and most easily digestible animal protein and was obtained from natural sources from time immemorial for consumption by human beings. However, due to over exploitation and pollution, the availability of fish in natural waters have declined considerably forcing scientists to adopt various methods to increase its production. Fish farming in controlled or under artificial conditions has become the easier way of increasing the fish production and its availability for consumption. Farmers can easily take up fish culture in village ponds, tanks or any new water body and can improve their financial position substantially. It also creates gainful employment for skilled and unskilled youths. The technology developed for fish culture in which more than one type of compatible fishes are cultured is the most advanced technique and popular in the country. This technology is

known as Composite Fish Culture. This technology enables to get maximum fish production from a pond or a tank through utilization of available fish food organisms in all the natural niches, supplemented by artificial feeding. Any perennial fresh water pond/tank retaining water depth of 2 metres can be used for fish culture purpose. However, the minimum level should not fall below one metre. Even seasonal ponds can also be utilised for short duration fish culture.

Here, fingerlings of fast growing compatible species of fishes with different feeding habits are employed. Indian major carps such as *catla catla* (catla,) *Labeo rohita* (rohu), and *Cirrhina mrigala* (mrigal) and exotic carps such as silver carp (*Hypophthalmichthys molitrix*), common carp (*Cyprinus carpio*) grass carp (*Ctenopharyngodon idella*) are stocked together.

1. Fish species involved in composite fish culture:-

Depending on the compatibility and type of feeding habits of the fishes, the following types of fishes of Indian as well as Exotic varieties have been identified and recommended for culture in the composite fish culture technology:

Indian Major Carp (IMC)

Species	Feeding habit	Feeding zone
Catla	Zoo plankton feeder	Surface feeder
Rohu	Omnivorous	Column feeder
Mrigal	Detritivorous	Bottom feeder

Exotic carps

Silver carp	Phytoplankton feeder	Surface feeder
Grass carp	Herbivorous	Surface, column and marginal areas
Common carp	Detritivorous/Omnivorous	Bottom feeder

2. Potential: The area under tanks and ponds available for warm fresh water aquaculture is estimated to be 2.85 million ha. In addition 0.78 million ha of swamps, beels, etc. and low lying water logged area not good for agriculture as also any agriculture land can be converted for fish farming. Out of the total inland fish production around 60% is contributed by the culture sector. The average productivity from ponds at present is to the tune of 2160 kg/ha/year. This shows the tremendous scope for fish culture in the country. The area of 4.56 lakh ha brought under scientific fish culture by 1997-98 is only 16% of the potential area of tanks and ponds available for development showing immense possibilities for horizontal expansion of composite fish culture.

Technical parameters that needs to be considered for Composite Fish Culture

1. Selection of Pond:

The main criteria to be kept in mind while selecting the pond is that the soil should be water retentive, adequate supply of water is assured and that the pond is not in a flood prone area. Derelict, semiderelict or swampy ponds can be renovated for fish culture by dewatering, desilting, repair of the embankments and provision of inlet and outlet. The pond may be owned by the individual or taken on lease in which case the lease period should be more or coterminous with the repayment period.

2. Pond Management:

Pond Management plays a very important role in fish farming before and after the stocking of fish seed.

A) Prestocking:

In case of new ponds, prestocking operations starts with liming and filling of the pond with water. However, the first step for existing pond requiring development deals with clearing the pond of unwanted weeds and fishes either by manual, mechanical or chemical means. Different methods are employed for this.

- Removal of weeds by Manual/Mechanical or through Chemical means.
- Removal of unwanted and predatory fishes and other animals by repeated netting or using mahua oil cake @ 2500 kg/ha meters or by sun drying the pond bed.

- **Liming:**-The tanks which are acidic in nature are less productive than alkaline ponds. Lime is used to bring the pH to the desired level. In addition lime also has the following effects -

- a) Increases the pH.
- b) Acts as buffer and avoids fluctuations of pH.
- c) It increases the resistance of soil to parasites.
- d) Its toxic effect kills the parasites.

B) Fertilization:

Fertilization of the pond is an important means of intensifying fish culture by increasing the natural productivity of the pond. The fertilization schedule has to be prepared after studying the quality of the pond soil. A combination of both Organic and Inorganic fertilizers may be used for best results. The fertilizer programme has to be suitably modified depending on the growth of the fish, available food reserve in the pond, physico-chemical conditions of the pond and climatic conditions.

C) Manuring:

- i) Organic manuring may be done in monthly installments @ 1000 kg/ha.
- ii) Inorganic fertilization may be done at monthly intervals alternating with organic manuring. However, the monthly rate of fertilization will depend on pond productivity and the growth of the fishes. It should be ensured that excess fertilization does not take place which may result in eutrophication.

D) Harvesting:

Harvesting is generally done at the end of first year, when the fishes attain average weight of 750 gm to 1.25 kg. A production of 4 to 5 tons/ha can be obtained in a year. However, for the purpose of working out economics' a production level of 3 tons/ha/year may be considered. Harvesting is done by partial dewatering and repeated netting. In some cases complete dewatering of ponds is resorted to.

3) Vertical expansion of fish culture:

A number of measures are now being employed by the entrepreneurs to increase the per hectare production of fish. Important measures adopted are stocking of Yearlings by stunning the growth of fish seed during first year, heavy stocking and multiple harvesting after the fishes attain a size of 500 gm. multiple stocking and multiple harvesting, use of aerators, integrated fish farming with animal husbandry activities like dairy, poultry, piggery or duckery to get daily organic manuring to the pond thus increasing its fertility. It is possible to increase the per hectare production of fish to 7 to 10 tons per ha per year by employing different methods as indicated above.

1.3.3 LAYOUT OF FISH FARM AND ITS MANAGEMENT & THE BY-PRODUCT OF FISHING INDUSTRY

Fish farming or pisciculture involves raising fish commercially in tanks or enclosures such as (fish ponds), usually for food. It is the principal form of aquaculture, while other methods may fall under mariculture. Farming carnivorous fish, such as salmon, does not always reduce pressure on wild fisheries. A facility that releases juvenile fish into the wild for recreational fishing or to supplement a species' natural numbers is generally referred to as a fish hatchery. Worldwide, the most important fish species produced in fish farming are carp, tilapia, salmon, and catfish.

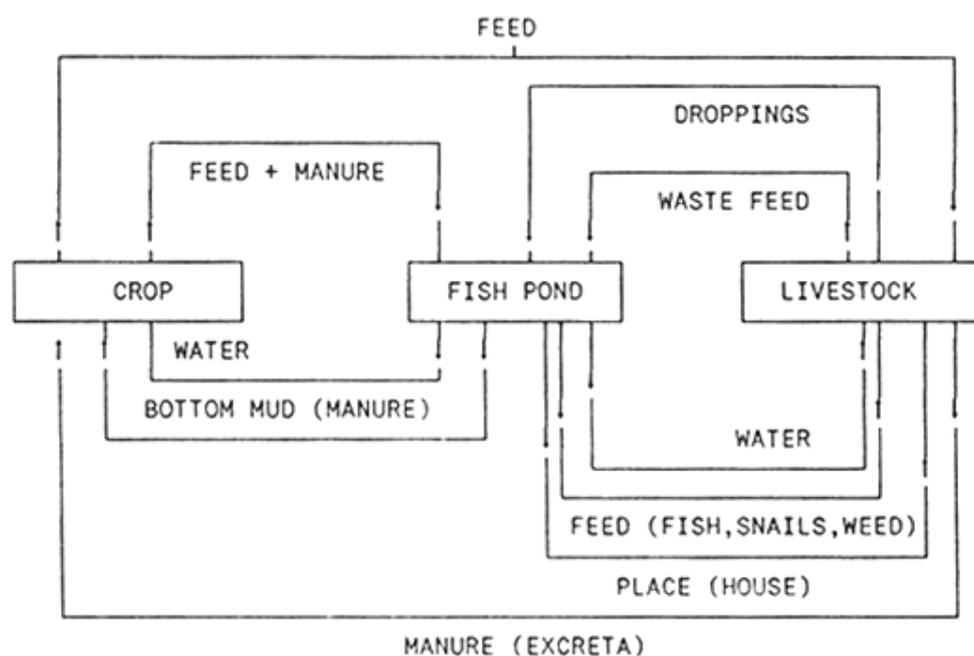

Fig.1.3 Diagrammatic representation of Layout of fish pond

Within intensive and extensive aquaculture methods, numerous specific types of fish farms are used, each has benefits and applications unique to its design. The traditional fishery by-products are fishmeal, fish body and liver oils, fish maw, etc. Fish protein concentrate, fish albumin, glue, gelatine, pearl essence, peptones, amino acids, proteins, fish skin leather etc. are some other by-products generally processed out of fish and fish waste. Fish and other aquatic organisms are also processed into various food and non-food products.

By-Product of fishes:-

Fishes are consumed as food in fresh condition. Some of them are also utilized after the preservation. During preservation and processing, some materials of fish and prawn are discarded as waste. Similarly some trash and distasteful fishes are unsuitable for human consumption. These waste material and above fishes become an important source of fish by-products, which in turn are used to produce different useful fish by-products. A shimmery substance found on fish scales, most usually obtained from herring and one of many by-products of commercial fish processing, can also be used for pearlescent effects, primarily in nail polish, but is now rarely used due to its high cost, bismuth oxy-chloride flakes being used as a substitute instead.

- Fish protein concentrate (FPC) is a stable protein concentrate prepared from whole fish or other aquatic animals or parts thereof. Protein concentration is increased by removal of water, oil, bones and other materials. Traditionally dried or otherwise preserved products do not fall within this definition. Development of FPC has paved the way for converting a wide range of whole fish into protein concentrate, which has no resemblance to the original raw material, for human nutrition.
- Fish Protein Concentrate is a gritty, colorless, odorless and tasteless powder. It is stable up to 3-4 years at room temperature without any significant change in flavour. Proximate composition of a representative sample of FPC is given below. The greater quantity of highly digestible protein, available lysine and minerals makes FPC a highly nutritious product.

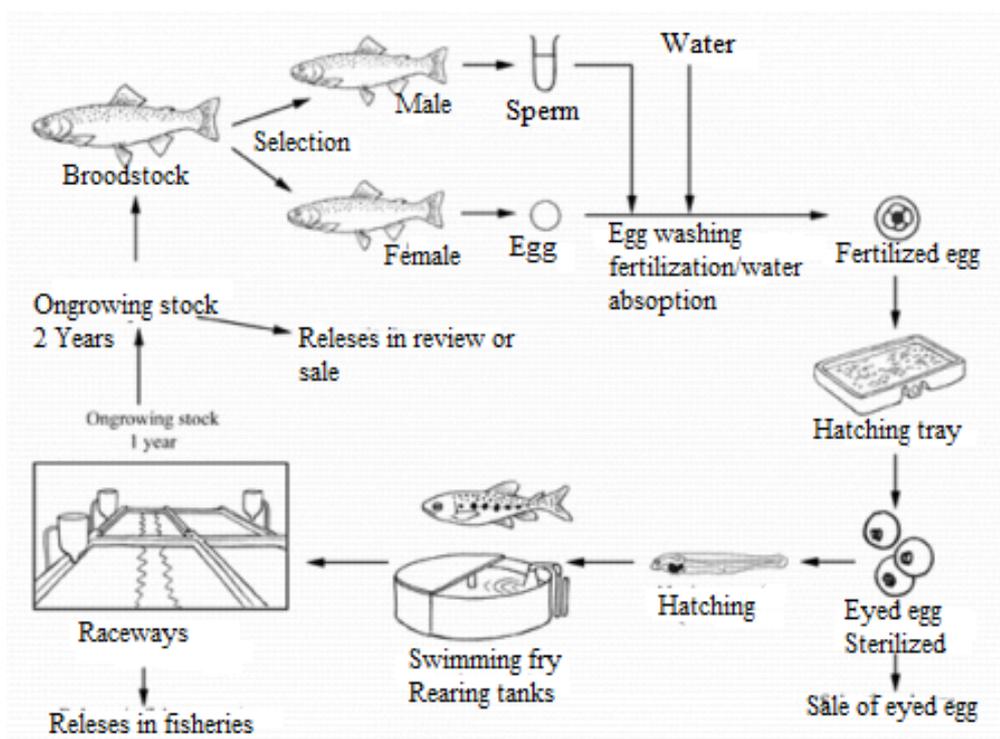

Fig 1.4 Production cycle of fish

Uses of By-product:-

- Though FPC is intended for human consumption it is not relished for consumption as such. It is therefore incorporated as a protein supplement in human diet. 5-10 per cent level FPC in bread and biscuit is considered the acceptable limit. 35 g per person per day is a recommended level of use of FPC.
- Fish undoubtedly is one of the most nutritious foods available for human consumption. Fish flesh on an average contains 15-20 per cent protein. Some species of fish contain very high amounts of body oil. Few species of fish like shark, cod etc. are good sources of liver oil. Fish processing and filleting industries turn out large quantities of fishery waste. All these are good sources of high quality protein, fat, minerals etc.
- The traditional fishery byproducts are fishmeal, fish body and liver oils, fish maw, isinglass etc. Fish protein concentrate, fish albumin, glue, gelatin, pearl essence, peptones, amino acids, protamines, fish skin leather etc. are some other byproducts generally processed out of fish and fish waste. Chitin and chitosan processed out of shrimp, crab and other crustacean waste are byproducts of high economic value.

Biochemical and pharmaceutical products like bile salts, insulin, glucosamine etc. are some other fishery byproducts of great significance.

1.4 PRAWN CULTURE

Prawn is a common name for small aquatic crustaceans with an exoskeleton and ten legs (i.e. a member of the order decapods), some of which can be eaten. The term "prawn" is used particularly in the United Kingdom, Ireland, and Commonwealth nations, for large swimming crustaceans or shrimp, especially those with commercial significance in the fishing industry. Shrimp that fall in this category often belong to the suborder Dendrobranchiata. A freshwater prawn farm is an aquaculture business designed to raise and produce freshwater prawns or shrimp¹ for human consumption. Freshwater prawn farming shares many characteristics with and many of the same problems as, marine shrimp farming. Unique problems are introduced by the developmental life cycle of the main species (the giant river prawn, (*Macrobrachium rosenbergii*)).

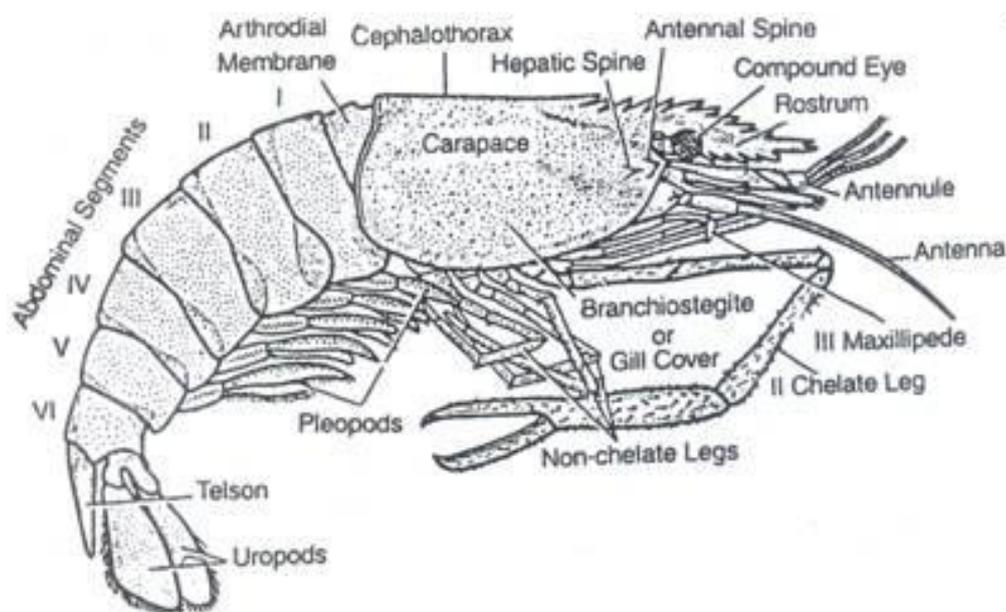

Fig.1.5 External feature of Palaemon

Habit, habitat and food of Prawns:-

Before going for the prawn culture we should have some knowledge about the habit, habitat and food of prawns. Prawn inhabits all sorts of water, much as in sea-water, estuaries and fresh-water. They are generally living at the bottom of water and are avoiding sun-rays. The

marine and brackish water species spawn in sea. The hatchlings are incapable to swim, so they are drifted along with the current to the coastal waters or estuaries where they undergo development till they reach the juvenile stage. The post larvae feed upon the dead organic matter of plants and animals and upon small benthonic organisms. The juvenile prawn has to enter the sea. The fresh-water species like *Macrobrachium* sp. spawn in fresh-water, and then they are drifted to estuaries and after attaining the juvenile stage swim back to fresh-water. Prawns are consuming the organic substances, microscopic animals and plants as their food material. Among the animals, minute insect, snail, larvae of mollusca and echinodermata as well as aquatic weeds, algae, moss etc., are taken as their food material.

Giant river prawns live in turbid freshwater, but their larval stages require brackish water to survive. Males can reach a body size of 32 cm and females grow to 25 cm around. In mating, the male deposits spermatophores on the underside of the female's thorax, between the walking legs. The female then extrudes eggs, which pass through the spermatophores. The female carries the fertilized eggs with her until they hatch; the time may vary, but is generally less than three weeks. A large female may lay up to 100,000 eggs. From these eggs hatch zoeae, the first larval stage of crustaceans. They go through several larval stages before metamorphosing into post larvae, at which stage they are about 8 mm long and have all the characteristics of adults. This metamorphosis usually takes place about 32 to 35 days after hatching. These post larvae then migrate back into freshwater.

Fig.1.5 Freshwater prawn farming

Prawn Culture in Fresh water

The culture of prawn is done in three ways, extensive, semi intensive and intensive.

In extensive culture the juvenile prawns are trapped from their natural habitat and are allowed to develop in some artificial water bodies e.g. rice fields. Here the prawns feed and grow till they are harvested. In the semi-intensive culture the juveniles are trapped from the conditions in the water bodies. Required size prawns are then collected for marketing.

Intensive culture requires much time and infrastructure to reap good results. Here the culture proactive starts from very beginning i.e., from spawning and culminate into the harvesting. All the factors required for the development and growth of prawns are carefully regulated and monitored here.

The economically important culturable varieties of freshwater prawns in India are giant fresh water prawn (*Macrobrachium rosenbergii*) and monsoon river prawn (*macrobrachium malcolmsonii*). The giant fresh water prawn is of prime importance due to its large size, fast growth, and excellent food value and consumer preference.

Distribution:

The prawns inhabit wide range of environmental conditions in tropical and sub-tropical zones. In nature, they migrate to estuarine zone for breeding and the juveniles (15-25mm) migrate back to the freshwater.

Food habits:

The prawns are omnivorous and eat frequently. They commonly feed on aquatic worms, insects and their larvae, small sized molluscs and crustacean, flesh and offal fish and other animals, grain, seeds algae and tender leaves and stems of aquatic plants.

Life cycle

The gaint fresh water prawn and the monsoon river prawns attain sexual maturity in 5 to 7 months in fresh water. They breed throughout the year with a peak at beginning of rainy season. The copulation takes place between the hard shelled sexually matured male and fresh moulted female (Premating moult). The male deposits its sperms on the ventral surface of the

female's cephalothorax close to the genital orifice so that, the eggs are fertilized as they are liberated through the female genital pores. Then the fertilized eggs are transferred to the brood chamber which is formed by the downward prolongation of the abdominal shell. The berried females descend to the brackish water of the rivers (estuary) for spawning.

Each female lays 5000 to 30000 eggs. Smaller females (8-10 g) lay 500-600 eggs/g and large females (60g) lay 300-400 eggs/g. The eggs appear bright orange in colour in the beginning, becoming progressively brown turning grey and finally becoming dark grey before hatching. The eggs are carried by the female in its brood chamber for 15 to 25 days depending on the water temperature. The larvae are liberated in water after hatching. The larvae pass through 11 developmental stages before changing into post-larvae. The larvae are planktonic and develop in brackish water for 3 to 6 weeks depending on the water temperature. The post larvae resemble the miniature adult prawns and develop the habit of crawling rather than free swimming and benthic in behaviour. These post larvae begin to migrate upstream into freshwaters within one or two weeks after metamorphosis and are able to swim against water current.

Seed:

The seed is obtained from two sources. The seed collection from natural water is carried out from rivers. The other method is to induce breed the prawns under controlled conditions in the hatchery.

Nursery Phase:

Nursery phase is an intermediate step between hatchery and culture ponds. In this, the post larvae (1.0cm) produced in hatchery or collected from natural resources are reared in specially prepared nurseries so as to grow them into juveniles (2.0 to 3.0 cm.) Nurseries may be earthen ponds, cement cisterns, or plastic pools enclosing a space of 50 to 200m².

Before stocking in nurseries, the post-larvae are thoroughly acclimatised to freshwater conditions by subjecting them to low level of salinity. Nurseries are stocked @ 2000 to 3000 post-larvae per m². Post-larvae at this stage tend to cling to any available surface inside the nurseries. In order to provide more surface for clinging, bunches of polythene strips are placed in nurseries with the help of sinkers.

Pond:

Ponds of 0.1 to 0.2 ha area is ideal for the culture of freshwater prawns. The pond bottom should be slightly sloping with a sump made at the deeper end to facilitate harvesting. Rectangular ponds having a length with ratio of 2.5:1 are desirable for easy netting during harvesting. The pond depth should be within a range of 0.75 to 1.2 m. To prevent erosion proper bundhs should be constructed. The internal and external slopes of the bundhs should be 2:1 to 3:1 and 1.5:1 to 2:1 respectively. Proper inlet and outlet should be provided in opposite direction at shallow and deeper ends of the pond respectively.

Water:

Water supply and its quality are of vital importance for prawn's culture. Criteria for water suppliers for prawn farming are as follows:-

pH: 7.0-8.5, Total hardness (CaCO_3) 50 to 100 ppm, Temperature 18° - 34° C (optimum 29° - 31° C), Dissolved oxygen more than 4.00 ppm, Salinity 0.25 to 0.75 ppm, Calcium Less-than 100 ppm, Phosphorus Less than 1 ppm, Nitrates Less than 1 ppm. The water intake through the inlet pipe should be screened, in order to supply sediment free water and prevent entry of small fish, eggs, larvae etc. into the pond.

Pond Management

Preparation of pond: Ponds are prepared in the same manner as it is done for carps involving steps like removal of predators, clearance of weds, liming and fertilization with organic manures. The pond is lime @ 250 to 500kg of chicken droppings per hectare). This organic base on the bottom increases the fertility of the pond and enhances the production of benthic organisms which is the prime natural food of the prawns.

Stocking:

Ten to fifteen days after liming and fertilization, prawn seed is stocked. Generally, 3 to 4 weeks old post-larvae to the prevailing water temperature in the pond by floating the polythene bags containing seed in the pond for 15 to 20 minutes before emptying then into the pond. Seed should not be stocked when water temperature is below 20° C. The optimum temperature for stocking is 22° to 24° C.

Stocking rate:

The recommended rate of stocking for monoculture operations is 7,000 10,000 per hectare and for polyculture with carps, just half of this number (15,000 to 25,000 per hectare.) In India, polyculture with carps is more preferred as it gives better scope for utilisation and conversion of natural and supplementary food and thus works out more economical. Compatible fish fingerlings viz. Catla, rohu, silver carp and grass carp are stocked @15, 00 to 2,000 per hectare before stocking the prawn sed.

Feeds:

The prawns feed actively at night and rest during the day. Natural feeds in culture ponds serve as a good source of food for the stocked prawns However, in commercial operations, the natural productivity is not sufficient where the prawns are stocked at higher densities. Therefore, it is essential to provide supplementary feed for achieving higher growth.

Feeding rate:

The quantity of feed is adjusted through trial and error. To avoid cannibalism, the prawns are not kept hungry. Good practise for the farm operator is to feed the animals according to their demand. Feeds are placed in wide plastic trays or earthen troughs kept at several points along the marginal shallow area. In monoculture, feed conversion ratio is 1:7-9 when raw (wet) feeds are used. Feeding with compound dry feeds ration of 1:2-3 has been obtained. Growth and survival: Growth and survival depends on a number of factors like food, stocking density, water quality, climate, pond size and productivity of pond.

1.5 PEARL CULTURE

Pearls are made by molluscs, like oysters. Pearls are small and often white but sometimes in pale colours or even black. They are often rounding, but sometimes half-round, oval, or in different shapes. Pearls are often used for jewellery. A cultured pearl is a pearl created by an oyster farmer under controlled conditions. Cultured pearls can be farmed using two very different groups of bivalve mollusk, the freshwater river mussels, and the saltwater pearl oysters. A pearl is formed when the mantle tissue is injured by a parasite, an attack of a fish or another event that damages the external fragile rim of the shell of a bivalve or gastropod mollusk. In response, the mantle tissue of the mollusk secretes nacre into the pearl sac, a cyst that forms during the healing process. Chemically

Fig.1.6 various pearl

speaking, this is calcium carbonate and a fibrous protein called conchiolin. As the nacre builds up in layers of minute aragonite tablets, it fills the growing pearl sac and eventually forms a pearl.

Physical properties of pearl:-

The unique luster of pearls depends upon the reflection, refraction, and diffraction of light from the translucent layers. The thinner and more numerous the layers in the pearl, the finer the luster. The iridescence that pearls display is caused by the overlapping of successive layers, which breaks up light falling on the surface. In addition, pearls (especially cultured freshwater pearls) can be dyed yellow, green, blue, brown, pink, purple, or black. The very best pearls have a metallic mirror-like luster. Because pearls are made primarily of calcium carbonate, they can be dissolved in vinegar. Calcium carbonate is susceptible to even a weak acid solution because the crystals of calcium carbonate react with the acetic acid in the vinegar to form calcium acetate and carbon dioxide.

Natural Pearl

Natural pearls are nearly 100% calcium carbonate and **Conchiolin**. It is thought that natural pearls form under a set of accidental conditions when a microscopic intruder or parasite enters a bivalve mollusk and settles inside the shell. The mollusk, irritated by the intruder, forms a pearl sac of external mantle tissue cells and secretes the calcium carbonate and conchiolin to cover the irritant. This secretion process is repeated many times, thus producing

a pearl. Natural pearls come in many shapes, with perfectly round ones being comparatively rare.

Typically, the build-up of a natural pearl consists of a brown central zone formed by columnar calcium carbonate (usually calcite, sometimes columnar aragonite) and a yellowish to white outer zone consisting of nacre (tabular aragonite). In a pearl cross-section, these two different materials can be seen. The presence of columnar calcium carbonate rich in organic material indicates juvenile mantle tissue that formed during the early stage of pearl development. Displaced living cells with a well-defined task may continue to perform their function in their new location, often resulting in a cyst.

Cultured Pearls

Cultured pearls are the response of the shell to a tissue implant. A tiny piece of mantle tissue (called a graft) from a donor shell is transplanted into a recipient shell, causing a pearl sac to form into which the tissue precipitates calcium carbonate. There are a number of methods for producing cultured pearls: using freshwater or seawater shells, transplanting the graft into the mantle or into the gonad, and adding a spherical bead as a nucleus. Most saltwater cultured pearls are grown with beads. Trade names of cultured pearls are Akoya, white or golden South Sea, and black Tahitian. Most beadless cultured pearls are mantle-grown in freshwater shells in China, and are known as freshwater cultured pearls.

Cultured pearls can be distinguished from natural pearls by X-ray examination. Nucleated cultured pearls are often 'preformed' as they tend to follow the shape of the implanted shell bead nucleus. After a bead is inserted into the oyster, it secretes a few layers of nacre around the bead; the resulting cultured pearl can then be harvested in as few as six months.

When a cultured pearl with a bead nucleus is X-rayed, it reveals a different structure to that of a natural pearl. A beaded cultured pearl shows a solid center with no concentric growth rings, whereas a natural pearl shows a series of concentric growth rings. A beadless cultured pearl (whether of freshwater or saltwater origin) may show growth rings, but also a complex central cavity, witness of the first precipitation of the young pearl sac.

Pearl Formation

Natural pearls are formed by nature, more or less by chance. On the other hand, cultured pearls are human creations formed by inserting a tissue graft from a donor oyster, upon which a pearl sac forms, and the inner side precipitates calcium carbonate, in the form of nacre or "mother-of-pearl". The most popular and effective method for creating cultured pearls are made from the shells of freshwater river mussels harvested in the midwestern states of the U.S., from Canada to the Gulf of Mexico. Shells with the common names, "Washboard" "Maple Leaf" "Ebony" "Pimple back" and "Three Ridge" are popular for use in pearl culture due to their compatibility with the host animal, and the nacre they are to be covered by. These high-quality and sought-after shells are first sliced into strips and then into cubes. The edges and corners are ground down until they are a roughly spherical and then milled to become perfectly round, and brought to a highly polished finish.

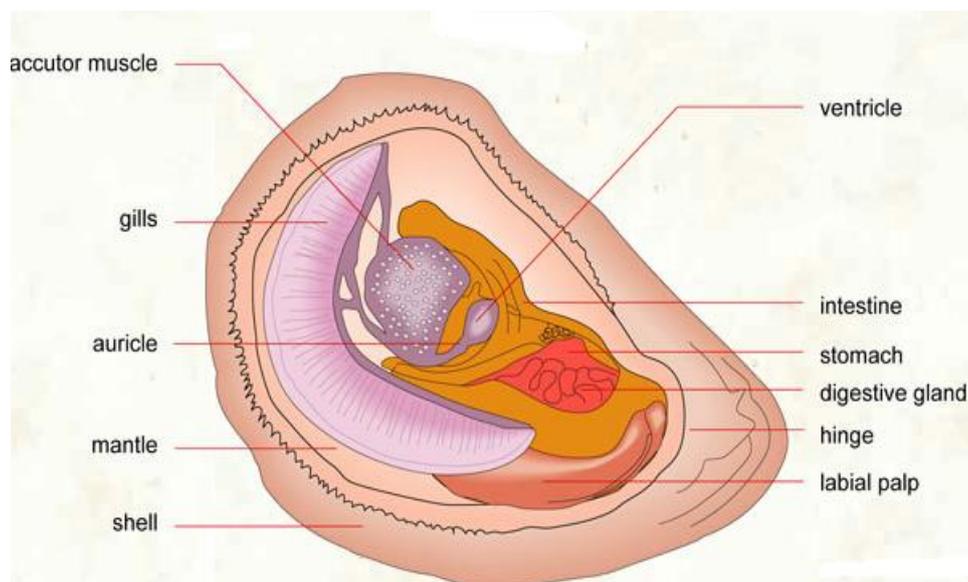

Fig.1.7 Oyster

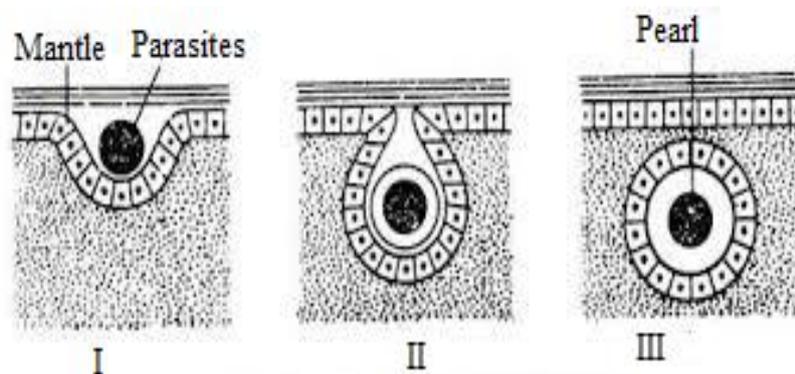

Fig.1.8 Stage in pearl formation

After the nucleus is ready, the next step is obtaining the mantle tissue. The mantle tissue is harvested from one oyster and cut into small pieces. After obtaining the mantle tissue from the first oyster it is time to operate on the second animal. The oyster is placed in warm water to relax the animal. Then it is gently pried open and mounted in a stand to be operated on. A small incision is made and the nucleus is inserted along with a small piece of mantle gland. The oyster is then placed back in the water and allowed over several years to coat the nucleus with nacre. The nucleus is coated in many layers of this nacre, so that when pearls are cut in half, visible layers can be seen.

Pearl Producing Molluscs:-

Although a number of bivalves have the ability to produce pearl under suitable climatic condition, high quality pearl obtained only from pearl oysters of genus *pinctada* roding belonging to the class *Bivalvia* and family *pteriidae*. A number of species of this genus like *P.vulgaris*, *P.chemnitzii*, *P.margaritifera*, *P.anomioides* etc. are found in India water. *P.vulgaris* is a common oyster distributed in the gulf of kutch, gulf of mannar and the palk bay.

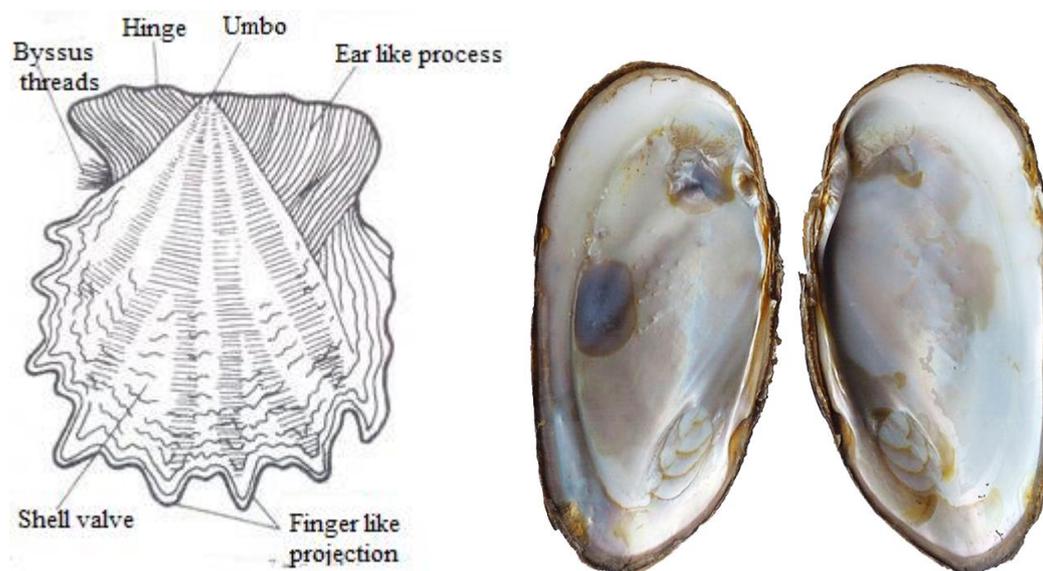

Fig.1.9 External feature of pearl oyster

Apart from the true pearl oyster belonging to the genus *Pinctada* a large number of the other marine and a few fresh water mollusks are also found to produce pearls. Mostly the pearl oyster inhabits on the ridges of rocks and dead corals forming extensive pearl banks at a depth of 18 to 22 meters.

1.6 TERMINAL QUESTION

- Give detail account of the Aquaculture?
- Give detail account of the composite fish culture?
- Write a short note on the By-product of fishing Industries?
- Explain the layout of fish farm with suitable diagram?
- Write a short note on the pond management?
- Give principles of Aquaculture?
- Give detail account of the culture of fresh water prawn?
- Give an account of the method of prawn fishing
- Give detail account of the pearl culture?
- Give detail account of the management of the fish culture programme?
- Give detail account of the induced breeding?

2.1 OBJECTIVES

Study of Different kinds of silk producing insect and the Host plant of Insect and motivating the students to plant high yielding mulberry varieties to increase income and productivity. Imparting training in mulberry cultivation, silkworm rearing and silk reeling. Enhance skill of students for increased productivity and to prevent silkworm diseases.

2.2 INTRODUCTION

Sericulture is the art and technology of raising silkworms for the production of raw silk. The word Sericulture is derived from the Greek word *Sericos* (meaning silk) and the English word Culture (meaning Rearing). There are several species of silkworms but the most extensively studied silkworm is *Bombyx mori*. It is an agro based cottage industry, but each person involved in it must have some technical knowledge about it. It requires enough patience, ability to adapt to new scientific development, etc. Sericulture, or silk farming, is the cultivation of silkworms to produce silk. Although there are several commercial species of silkworms, *Bombyx mori* (the caterpillar of the domesticated silk moth) is the most widely used and intensively studied silkworm.

2.3 DIFFERENT KIND OF SILK PRODUCING INSECT

Mulberry Silk worm (*Bombyx Mori*)

Mulberry silk is the most common among the many kinds of silk. It makes up 90% of the silk supply in the world. This popular kind is produced by the ***bombyx mori* silkworms** which are fed from the mulberry bush (thus the name). Since it is a common kind of silk, acquiring it is easy. Countries such as China, Japan and Korea have an abundance of it in particular. One of the disadvantages of using this kind of silk is that it needs special care to maintain its smooth texture. It also is often obtained in an unethical way, by killing the silkworms in their cocoons to extract the long fibres. For more information on this, have a look at our article **The Pros and Cons of Silk Production**, which also includes information on vegetarian silks, or **'Peace Silks'**.

Tussar Silk worm

Tussar silk worm *Antheraea paphia* belongs to the family Saturniidae. Tussar silk is produced by **tussar silk worms**. Unlike other silks, this one has a distinct light golden to dark brown colour. This is a result of the tannin-rich leaves that tussar silkworms consume.

Muga Silk worm:-

Muga silk worm *Antheraea assamensis* is the semi-domesticated silk worm, **another member of the** same family Saturniidae. Muga originates in India, and the silk it is known for its golden brown and glossy texture. Along with the Eri (below) and Pat silk, Muga silk is sometimes referred to as Assam silk, as fabrics produced from these silkworms were reserved for the exclusive use of royal families in Assam. Muga's silk porosity can sometimes become a disadvantage as it limits the use of bleach (which for us more eco-conscious types is an advantage!) but also means that it can't be dyed. Silk is said to be one of the strongest fibres around – and it's certainly the case with these thicker tussars and makes it an ideal material for couches, jackets and sweaters.

Eri Silk worm:-

Eri silk is derived from the domesticated silkworm *Philosamia rinini*. It is a fine silk that is almost as white in colour as the *Bombyx mori* (Mulberry Silk we talked about above). Even though Eri is spun from the cocoons of domesticated silk worms, it is a “peace silk” because the silk caterpillars are not destroyed in the cocoon but are allowed to emerge as moths and live a full lifecycle. Because the cocoons are damaged when the moth emerges, Eri silk is spun rather than reeled. It usually has the matt appearance of wool or cotton, but the sheen and softness of silk and is commonly cultivated in India, Japan and China. Aside from the *Bombyx mori*, this is the only other silkworm that is completely domesticated, so it relies on human intervention to be developed. And just like the *Bombyx Mori*, the name “Eri” is said to derive from the Assamese word “Era”, which means castor plant – the food that the worms feed on. This is a very durable silk and makes a great material for clothing, and surprisingly, soft furnishings such as curtains and couches. The only drawback of using such silk is the fact that it is heavy to wash. It may also harbor micro organisms as it is easier for them to stick on its thicker layers.

Mussel Silk:-

As the name implies, this silk is produced by mussels – yes, the same ones that can be found on seabeds. It is also sometimes called **Sea Silk**. This differs from the other silk types we've mentioned so far as it is not produced by silkworms. It is difficult to source this kind of silk nowadays due to the effects of pollution on its source. Since its production is rare, it counts as one of the most expensive silks to date. The most common type of mussel, or more accurately mollusk used in the production is the Byssus, and this fabric tends to be called **Byssus Cloth**. There is an amazing explanation of the fabrics and the differences between them here.

Spider Silk:-

Like Mussel silk, you may be surprised to learn that spider silk has long been used by ancient cultures. But unlike other types of silk, this is the most difficult one to produce as spiders cannot just be bred like silkworms. Spiders cannot produce as much yarn as silkworms either. But though the production of this type of silk may seem difficult, its output is certainly worth the effort. It is regarded as one of the most durable types of silk as it is now being utilized in the production of telescopes, bulletproof vests and wear-resistant clothing etc.

2.4 HOST PLANT OF INSECT

Host plants of tasar silkworm:-

The important food plants are Arjun (*Termanalia Arjuna* Roxb. Fr. De Wright & Am.), Asan (*Termanalia tomentosa*, W& A) and Sal (*Shorea robusta* Gaertn). Besides these, the silkworm feeds on Phutuka (*Melastoma melabathricum* Linn.), Bogori (*Zizyphus jujuba* Mill) etc, are some of the endemic species of the tropical region of India. The temperate species of this silkworm, namely as, *Antheraea proylei* Jolly, feeds on different species of Quercus which are widely distributed in this region.

Host plant of Mulberry silkworm: - Mulberry silkworm is a monophagous insect which reared on the leaves of mulberry only; the morin present in the leaves helps to attract the silkworm.

Host plants of Muga silkworm:- *Muga group comprises of Antheraea assama* Westwood, *A. knyvetty*, *A. compta* and *A. helferi* are endemic polyphagous insect and feeds on different host plant species, formerly named as *Machilus bombycina* (King ex Hook. f.) and *Soalu*

(*Litsea monopetala*) and few other food plants, likewise Digloti (*Litsaea salicifolia* Hook), Mejankari (*Litsaea cubeba* Lour.), Bogori or ber (*Zizyphus jujuba* Mill), Champa (*Michelia champaca* Linn.), Bhomloti (*Symplocos grandifolia* Wall), Patihonda (*Actinodaphne obovata* Blume), Gamari (*Gmelina arborea* Linn.) Panchapa (*Magnolia sphenocarpa* Roxb.), Katholua (*Cyclicodaphne nitida* Roxb.), Gansarai (*Cinnamomum glanduliferum* Meissu), Bojramoni (*Xanthoxylum rhesta* DC.).

Host Plants of Eri Silkworm: - *Eri* group comprises of *Eri* (*Samia ricini* Donovan and *Samia Cynthia*) is widely available. Besides this wild silkworms like *Attacus atlas* and *Cricula* species are distributed in this region. Castor (*Ricinus communis* Linn.) is primary food plants of *Eri* silkworm and commonly distributed in this region. However, Kesseru (*Heteropanus fragrans* Roxb.) is also considered as another primary perennial food plants. Besides these two, *Eri* silkworm being polyphagous feeds on several alternative food plants viz. Borkesseru (*Ailanthus excels* Roxb.), Barpat (*Ailanthus grandis*), Topioca (*Manihot esculanta* Crantz), Gulancha (*Plumeria acutifolia*), Gamari (*Gmelina arborea*), Payam (*Evodia flaxinifolia*), are endemic to this region.

2.5 REARING & DISEASE OF SILKWORM

The word rearing does not mean only the feeding of caterpillars as often understood but a continuous care from egg laying through aestivation, hibernation, incubation, early stage larval care, late stage larval care, late stage larval to the production of cocoon. So, for proper and step-wise study of rearing one should proceed from Grainage Technology.

Grainage Management

The aim of establishment of grainage is to provide good quality of seed to rearers and maintenance of original quality of races. For this purpose due care should be taken of the 'crop of silkworm' for seed production from the very beginning' i.e., the caterpillar stage, by providing them with proper nutrition and protection from the attack of diseases. Keeping these points in view initial selection is made on the basis of percentage of dead pupae during normal development. If it is above the limit seed should not be purchased for seed production. First selection is made by separating out dead cocoons and next selection in the grainage.

After grainage management the next step is the supply of seed of caterpillars to the farmers. The supply is of two types depending on the knowledge of rearers i.e., supply of eggs and 2nd instar larvae.

The old rearers who are well versed with the rearing technique may purchase eggs for the rearing but new and untrained rearers knowing nothing about the rearing should always be given 2nd instar caterpillars for this purpose. Much care should be taken for the rearing of 1st, 2nd and 3rd instar caterpillars and 4th and 5th instar caterpillars are mostly reared either on hanging trays often with nylon nets or on the floor.

Spinning of Cocoons

This is the period when the caterpillar stops feeding and starts to secrete a pasty substance from the silk gland. In this condition worms should be picked up and transferred to the spinning trays and kept in a position of slope (slanting) to the sun for a short period. Within three days spinning is over and the cocoon is formed and this is the last phase of the rearing of silkworm.

Quality of cocoon: The quality of cocoon is dependent on the raw silk yield, filament length, and real ability and splitting.

Marketing of cocoon: The price of cocoon is fixed during every season of the rearing. This price is, however, watched by the Government and cocoons are purchased by the rearers.

Post-cocoon processing

The method of obtaining silk thread from cocoon is known as post-cocoon processing. This includes Stifling and Reeling.

1. **Stifling:** The process of killing the cocoons is termed as stifling. Seri culturists should be very much careful that before the emergence of silkworm (The cocoons which do not have cut holes.) good sized cocoons of 8 to 10 days old are selected for further processing and dropped into hot water or subjected to steam or dry heat, sun exposure for 3 days or fumigation. In this way pupae or cocoons are killed. The killing of the cocoon in boiling water helps in softening the adhesion of the outer threads to separate freely, facilitating the unbinding of silk threads.

2. **Reeling and spinning:** The process of removing the threads from the killed cocoon is called as reeling. Four or five free ends of the threads of these cocoons are passed through

eyelets and guides to twist into one thread and wound round a large wheel from which it is transferred to spools. Thus, the silk obtained on the spool is called as raw silk or reeled silk. The waste outer layer or damaged cocoons and threads are separated, teased and then the filaments are spun. This spun silk is called as 'Spun silk'.

1. Emergence of moth and fertilization: When kept for emergence at room temperature, mass emergence of adults takes place. As per their nature, just after emergence, male moth starts moving around the female. Males are very much active whereas the females which are loaded with eggs are incapable of flying. If not separated at once in cages males start copulating with the females but the eggs obtained from this female mated from the male of the same stock is useless for the seed. So the males and the females just after emergence have to be separated into separate cages without their mating. Now one female of one lot is kept with the male of the other lot and at once they form pair and copulate for about 3 hours. After completion of mating, males should be separated and may be used for the fertilization of other females. But one male cannot fertilize more than two females. Now fertilized females are subjected to egg laying.

2. Egg laying: Just after fertilization, female starts egg laying and in duration of 24 hours it completes egg laying process. The eggs laid by one female are about 400 to 500 varying according to the different races. Female dies after egg laying. These eggs are called as SEED. These eggs are kept in sterilized trays and stored at 4°C under laboratory conditions or sometimes kept at hill stations in diapause conditions.

3. Hatching: This is an important phase of sericulture industry because as soon as the larvae are hatched they start feeding voraciously. So only those Sericulturists who would be able to supply sufficient amount of fresh mulberry leaves to the young hatched larvae, could perform successful sericulture programme otherwise young ones will die resulting great loss to sericulture industry. This is why the hatching has to be controlled, accelerated or postponed by artificial treatments under refrigerated conditions. For proper hatching of seeds(eggs) advanced techniques have been developed in which eggs are collected and kept with mulberry leaves, working as stimulant for hatching in shady places on white sheet of paper in insect proof trays on a stool. For this purpose the legs of stool must be kept in water so that insects may not crawl and damage the hatching eggs. It is also notable that if the eggs are placed in the same position in which they are laid, hatching will not be 100%. So it is advisable that the eggs kept in trays should be moved with the help of feather. The group of

caterpillars hatched at various stages should be kept separately. Thus, one should be careful that hatching must be coincided with the best season of the mulberry.

4. Experimental data of egg laying and hatching:

If after 120 minutes of oviposition eggs are kept at 10⁰C for 24 hours then transferred to the oven at 16⁰C for 4 days and further soaked in hydrochloric acid (15% at 46⁰C) for 5 minutes.

Diseases of Silkworm

The Sericulture Industry suffers from a number of diseases in Tropical regions of South East Asia. The maggot disease, pebrine, polyhedrosis and flacherie are the diseases which cause severe damage to this industry. The poisoning by tobacco and Muscardines is also reported to be harmful but is not very common.

A. Maggot Disease

This disease is caused by *Tricholyga sorbillans*, a fly belonging to the order-Diptera and Family-Techinidae. It is distributed throughout India, Japan, Korea, China, Vietnam and Thailand. The presence of milky white cylindrical eggs on the skin of silkworm larvae is a symptom of this disease. The number of eggs laid by the fly on a silkworm larva varies from several to more than fifty but usually they are two to three. After 30-40 hours of egg laying, maggot makes a hole on the ventral side of egg shell and on the skin of the silkworm. Thus, maggot penetrates into the body of silkworm larvae and starts eating the tissues of larvae. When the maggot penetrates into the larval body, the big black mole is formed on that part of the skin. The segments in which maggot exists, swell up and bend as a result the attacked larva becomes inactive and loses appetite. Usually fourth and fifth stadia are attacked by the maggots. The larvae, attacked up to the fourth stadia die before making cocoon but usually do not attain the pupal stage.

B. Pebrine

This is one of the worst diseases of silkworm. Sericulture was once damaged by this disease in all the countries involved in this industry but some countries have overcome this disease and succeeded in getting pebrine-free-silkworm-eggs for reeling cocoons. *Nosema bombycis* Nageli, belonging to Microsporida, is the casual micro-organism of this disease. The infection takes place through the mouth of larvae at the time of feeding or through the mother's ovary. When new spores are formed in the tissues of alimentary canal of silkworm, they are discharged with the faeces and make a source of infection. When new spores are

formed in the tissues of alimentary canal of silkworm, they are discharged with the feces and make a source of infection. When the spore enters into the digestive tract of silkworm, two nuclei, contained in the sporoplasm, are divided into four nuclei and at the same time the polar filament projects and penetrates into the cells of the alimentary canal. Further, they enter into the blood and swim in it. They are distributed throughout the host body, attacking various tissues, specially the fat bodies and organs, excluding chitinous tissues and nucleus of cells. When the hypoderm is attacked and its cells die, the affected part becomes black due to the formation of melanin. Inside the body, the milky white spots or marks are observed on the silk gland or on the surface of the alimentary canal. In case of severe infection of the eggs the whole of yolk nearly gets filled with the micro-organisms resulting in their (eggs) death. Whereas, in case of slight infection the eggs hatch but the larvae carrying infection die at the third moult without making cocoon.

1. **Examination of mother moths:** All the mother moths producing eggs should be carefully examined one by one and eggs laid by healthy moths only be taken for further use. The unqualified eggs should be burnt away.

2. **Forecasting and correcting examination:** In order to make the pebrine examination more reliable, the forecasting and correcting examinations are carried out for the eggs of the seed cocoons.

The materials employed for forecasting examinations are the excrement of mature larvae, late moulting larvae, dead larvae, cocoons or pupae and moths accelerated to emerge out of cocoons. For the correcting examination a few eggs of each reproductive egg-batch are taken and incubated and thus, emerged larvae are used as the material for examination of pebrine germs.

3. **Removal and disinfection of pebrine germs:**

The spores of pebrine may survive for a number of years in an ordinary type of rearing room if the environmental condition is humid. Therefore, rearing rooms, tools and other utensils should previously be cleaned and washed to remove the pebrine diseased eggs, carcasses of infected larvae, pupae, moths and dead cocoons, faeces of diseased larvae and so on. The pebrine spores can be destroyed by treatment with 2% formalin for 30 minutes, 0.5% sublimate for 5 minutes, 5% chlorinated lime for 30 minutes, current steam for 30 minutes and sun shine in the summer for 7 hours.

4. **Care on rearing silkworms:** The tendency of the infestation by the pebrine spores has been observed to occur more when silkworms are reared in dry and cool conditions than in the hot and wet conditions. If the larval period becomes longer, the infection of pebrine is severe, so care should be taken on these points during the course of selection of the seed cocoons by the rearers.

C. **Polyhedrosis in Silkworms**

Three types of polyhedrosis are found in silkworms:

- (1) Nuclear polyhedrosis.
- (2) Intestinal cytoplasmic polyhedrosis.
- (3) Intestinal nuclear polyhedrosis.

1. **Nuclear polyhedrosis (Grasserie Jaundice):**

It is caused by a kind of virus which forms polyhedral in the nuclei of the cells of fatty tissues, dermal tissues, muscles, tracheal membranes, basement membrane, epithelial cells of midgut and blood corpuscles. The polyhedral are commonly hexagonal and rarely tetragonal in shape, containing large number of virus in them. The polyhedral into the body fluid. The virus present inside the polyhedral maintains its pathogenic power for a number of years in the rearing room but the isolated virus loses its pathogenic power in a period of short time.

2. **Intestinal cytoplasmic polyhedrosis:** This type of polyhedral are formed in the cytoplasm of midgut cells but in a few cases they are formed in the goblet, too. The polyhedron of this disease contains plenty of viruses. The infected cells of midgut rupture and polyhedral are released into the gut. Thus, the faeces, excreted become whitish, containing plenty of polyhedra.
3. **Intestinal nuclear polyhedrosis:** In this disease the virus makes polyhedra inside the cytoplasm and nucleus of the midgut cylindrical cells. The polyhedral formed in this disease are large sized. The translucent cephalothorax, shrinkage of body and diarrhea are the symptoms of this disease also. The mode of infection and countermeasures are similar to those of nuclear polyhedrosis.

D. Flacherie

Flacherie is the generic name of some kinds of silkworm diseases, carcasses of which rot due to the attack of bacteria. Flacherie may be divided as follows:

1. **Infectious flacherie caused by a kind of virus:** The various symptoms of flacherie are loss of appetite, translucent cephalothorax, vomiting and diarrhea but the real diagnosis can be made after the microscopic observation of the virus.

The pathogen of this disease is a spherical virus which does not form polyhedral in the body of silkworm larvae. The virus multiplies in the tissues of midgut and is released into the gastric juice and is excreted along with faeces which are the source of infection. The virus infects the larvae of silkworm orally.

Countermeasures:

- (1) Resistant silk worm races should be selected.
- (2) The rearing room, tools and utensils should be well disinfected.
- (3) In order to maintain the good health of silkworm, high quality mulberry leaves should be provided.
- (4) Favourable conditions like temperature and humidity should be maintained in rearing rooms.
- (5) The faeces, diseased larvae and dead bodies should be piled in the compost.
- (6) Some of the chemicals like hydrochloric acid, formalin, chlorinated lime may be used as disinfectants for this virus.

2. Gastric injury caused by physiological disturbance of silkworms followed by the multiplication of bacteria:

Due to the supply of bad quality of mulberry leaves the digestive physiology of the mulberry leaves the digestive physiology of the silkworm is disturbed and multiplication of bacteria in the gastric cavity takes place. Thus, the combined action of physiological disturbances and bacterial activity in the gut are major causes of this disease. In unfavorable climatic conditions, the bacteria like *Streptococci* sp. *Coli aerogenus* bacilli or proteus group bacilli attack the weakened silkworms.

The control measures against this disease are to keep healthy conditions of rearing silkworms.

3. Bacterial intoxication: This disease is caused by a toxin of some bacilli, *Bacillus thuringiensis* Var. The larvae attacked by this toxin become unconscious, later soften, become darkish and finally rot off. The infection occurs orally and can retain the toxicity as long as for seven years in some cases.

The countermeasures are the disinfection of the rearing room and instruments.

4. Septicaemia: This disease is caused by infection of some bacteria as *Bacillus megatherium*, *B. proteus*, *B. prodigiosus*, *B. pyocyones* in the blood of silkworms. This disease is rear in the larval stage but it causes severe damage to the pupae and the moths during the period of egg production. The infection is caused through the wounds on the skin.

E. Green Muscardine

It is a fungal disease of silkworms. There are a number of muscardine in silkworm but only green muscardine (*Spicaria prasina*) has been noticed to affect the larvae of silkworm in Vietnam.

The infection may be observed at the third and fourth stadia of silkworm. In the beginning stage a big black spot is observed on the ventral side.

The green-tubes of fungus develop into mycelia in the blood and bear cylindrical spores which are separated from mycelia and further form mycelia which bear cylindrical spores again. Thus, all the organs of silkworm are attacked by this fungus disturbing their normal functioning. As a result the diseased larvae do not moult and finally die.

2.6 REELING AND FIBER TECHNOLOGY

The process of removing the threads from the killed cocoon is called as reeling. Four or five free ends of the threads of these cocoons are passed through eyelets and guides to twist into one thread and wound round a large wheel from which it is transferred to spools. Thus, the silk obtained on the spool is called as raw silk or reeled silk. The waste outer layer or damaged cocoons and threads are separated, teased and then the filaments are spun. This spun silk is called as 'Spun silk'. The raw silk is further boiled, stretched and purified by acid or by fermentation and then carefully washed over again and again to bring about the well known luster on the thread.

The modernization of the reeling and spinning process by autolization and various labour saving processes has opened a new way to this cottage industry in the world.

Life History of Mulberry Silkworm, *Bombyx mori*

The adult of *Bombyx mori* is about 2.5 cm in length and pale creamy white in colour. Due to heavy body and feeble wings, flight is not possible by the female moth. This moth is unisexual in nature and does not feed during its very short life period of 2-3 days.

Fertilization: Fertilization is internal preceded by copulation. Just after emergence, male moth copulation. Just after emergence, male moth copulates with female for about 2-3 hours and if not separated they may die after few hours of copulating with female.

Egg lying: Just after copulation, female start egg laying which is completed in 1-24hours. One moth lays 400 to 500 eggs depending upon the climatic condition and the supply of food material to the caterpillar from which the female moth is obtained. The egg laying is always in form of clusters and covered with gelatinous secretion of the female moth which helps them in proper attachment.

Hatching: The egg after ten days of incubation hatch into a larva called as caterpillar. Hatching is the most important phase of silk moth's life. After hatching, caterpillars need continuous supply of food because they are voracious feeders. If proper supply of mulberry leaf is not possible the development of caterpillar would not be in proper course. Sometimes, due to lack of food material, young caterpillars die causing great loss to the sericulture industry. It is recorded that in uni-voltine race hatching of eggs takes one month after laying.

Caterpillar: The newly hatched caterpillar is about 0.3 cm in length and is pale, yellowish-white in colour. The caterpillars are provided with well developed mandibulate type of mouth-parts adapted to feed easily on the mulberry leaves. The caterpillar is twelve segmented and the abdominal region has ten segments having five pairs of pseudo-legs. It is also provided with a small dorsal horn on the anal segment. Because of its being very much tender, the 1st instar larva can feed only on very soft leaves of mulberry plants. As they are voracious feeders, they grow rapidly which is marked by four moultings caterpillars get changed into 2nd, 3rd, 4th and 5th instars respectively. It takes about 21 and 25 days after hatching. The full grown caterpillar is 7.5 cm in length. It develops salivary glands, stops feeding and undergoes pupation. The time taken for the full growth of the caterpillar from

young to the well grown stage varies with regard to the temperature, humidity, food supply and type of race. Weight of the full grown caterpillar varies from 4 to 6gm.

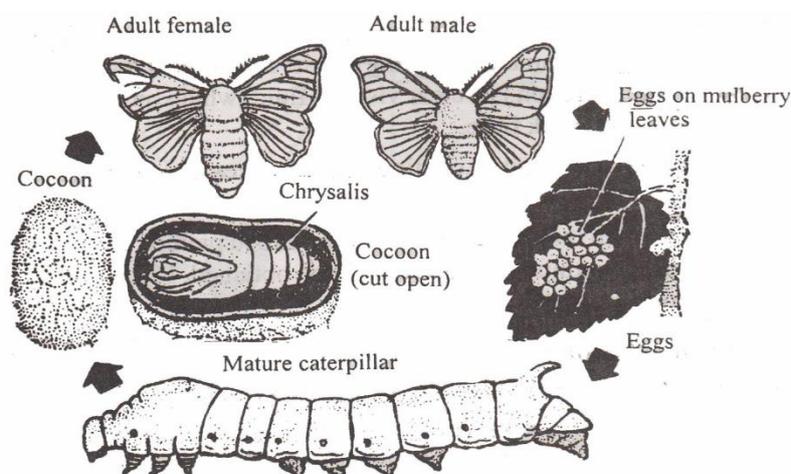

Fig 2.1 Life cycle of Silk worm

Pupa: The caterpillars stop feeding and move towards corner among the leaves and secrete a sticky fluid through silk gland. The secreted fluid comes out through spinneret (a narrow pore situated on the hypopharynx) and takes the form of long fine thread of silk which hardens around the body of the caterpillar in the form of a covering called as Cocoon.

Cocoon: Cocoon is the white colored bed of the pupa whose outer threads are irregular while the inner threads are regular. The length of continuous thread secreted by a caterpillar for the formation of cocoon is about 1000-1200 meters' which requires 3 days to complete. The threads are wound around the cocoon in concentric manner. The binding of threads round the cocoon is very interesting and quick going phenomenon achieved by the constant round motion of the head of the caterpillar from one side to the other at the rate of 65 times per minute. Now the silkworm pupa is covered within a thick, oval white or yellow silken cocoon. It is estimated from the data obtained by practical application that one pound of silk can be obtained from 2500 cocoons.

SILK

Silk is a pasty secretion of the silkworm produced by the silk gland. The silk gland is actually modified salivary glands which are long and sac like. As this pasty secretion comes in contact with air, it becomes hard and forms strong and pliable silk stands. This secretion forms two cores of fibroin: (i) a tough elastic insoluble protein consisting of 75% of the fiber's weight

and cemented together with sericin from the middle region of the silk gland at the time of secretion, and (ii) a gelatinous protein which is easily soluble in warm water. Some quantity of wax and carotenoid pigments are also detected. The diameter of the silk fibers is 0.0045 to 0.0082cm. Its elasticity is found to be 20%.

Economic Importance of Silk

The raw silk is used in the manufacture of woven materials and the knitted fabrics for the preparation of garments, parachutes, parachute cords, fishing lines, sieve for flour mills, insulation coil for telephones and wireless receivers and tyres of racing cars. Fabrics for garments in various weaves, plain, twill, stain, crepe, georgette and velvet, knitted goods such as vests, gloves, socks, stockings, dyed and printed ornamented fabrics for saris, jackets, shawls and wrappers are made out of this material.

Silk-Research Institutes

- (1) Central Sericultural Research and Training Institute (CSR and TI) Mysore (Karnataka).
- (2) Central Sericultural Research and Training Institute (CSR and TI) Berhampore (West Bengal).
- (3) Central Tasar Research and Training Institute (CSR and TI) Ranchi (Jharkhand).
- (4) Central Silk Technological Research Institute (CSTRI) Bangalore (Karnataka).

Regional Silk-Research Stations

A number of Research Centers have been established in different parts of the country for carrying out research in mulberry, oak tasar, muga and eri silk:

Mulberry Silk-Research Station

1. Bangalore (Karnataka)
2. Chamaraj Nagar (Karnataka)
3. Salem (Tamilnadu)
4. Coonoor (Tamilnadu)
5. Kalimpong (West Bengal)
6. Dhule (Maharashtra)
7. Pampore (Kashmir)
8. Anantpur (Andhra Pradesh)

9. Jorhat (Assam)
10. Ranchi (Jharkhand)
11. Koraput (Orissa)
12. Mothabari (West Bengal)
13. Majra (Uttar Pradesh)

Oak Tasar Silk Research Station

- (1) Batote (Jammu and Kashmir)
- (2) Bhimtal (Uttar Pradesh)
- (3) Imphal (Manipur)

Muga Silk Research Station

- (1) Bako (Assam)

Eri Silk Research Station

- (1) Mendipather (Meghalaya).

2.7 TERMINAL QUESTION

Question 1. Give an account of the species of the Silkworm and describe the life history of *Bombyx mori*.

Question 2. Give a detail account of the of silkworm disease.

Question 3. Describe the rearing of mulberry silkworm.

Question 4. Write a short note on the cocoon processing in sericulture.

Question 5. Write a short note on the maggot disease of silkworm.

3.1 OBJECTIVES

- To provide the knowledge to the learners about Apiculture
- To promote the formation of Bee Improvement groups.
- To liaise with bee-keepers with a view to establishing bee improvement groups.
- To advise and encourage bee-keepers to promote our aims and objectives.

3.2 INTRODUCTION

Beekeeping or apiculture is the maintenance of honey bee colonies, commonly in man-made hives, by humans. A beekeeper (or apiarist) keeps bees in order to collect their honey and other products that the hive produces (including bees wax, propolis, pollen, and royal jelly), to pollinate crops, or to produce bees for sale to other beekeepers. A location where bees are kept is called an apiary or "bee yard." Apiculture or beekeeping is the practice of maintaining honeybee colonies, usually in hives. This could be for collecting honey and beeswax, or for pollinating crops, or for the purpose of selling bees to other beekeepers. About 85 per cent crops plants are cross-pollinated, and colonies of honeybees, placed in the field when the crop is in flowering stage, can set about the needed pollination; abundance of pollinators helps in early setting of seeds, resulting in early and a more uniform crop yield.

3.3 HONEY BEES OF INDIA

Honey bee belongs to the class **Insecta**, order **hymenoptera** and family **apidae**. There are five well recognized types of bees found in the world.

- (i) *Apis dorsata* (Rock bee)
- (ii) *Apis florea* (Little bee)
- (iii) *Apis indica* (Indian bee)
- (iv) *Apis mellifica* (European bee)
- (v) *Apis adamsoni* (African bee)

Out of these five types, three are common in India. They are

1. *Apis dorsata*(Rock bee)
2. *Apis florea*(Little bee)

3. *Apis indica*(Indian bee)

Apis dorsata: - which is commonly called as rock bee, is the largest Indian variety with an average size of about 20 mm. It builds large comb (0.90 x 15 metres) on tree branches, under caves, or under roofs of high buildings. They are migratory species as during June and July they swarm to the hills, but in winter come back to the plains. They have been found up to the height of 3,500 feet above sea level.

This variety is yet to be successfully hived. Researchers are going on, on the behaviour of this variety in order to domesticate them. This variety has the highest honey yield (average 15 kg. per colony per year) amongst Indian bees. Sometimes, the yield exceeds 30 kg. Per colony per year. This bee is notorious for its ferocity and tendency to make unprovoked, sometimes fatal, mass attack on persons who approach its hive.

Apis florae: - which is commonly called as little bee, is a miniature of the rock bee. It is a plain species and rarely occurs above 1000 feet of sea level. It builds small comb (about 15.24 cm. across) on the branches of trees, or in bushes, or under the wall of the buildings. The yield of honey from this type is very little (few ounces per colony per year), and the production does not compensate the labour undergone on it.

Apis Indica: - Popularly known as Indian bee, is of commonest occurrence on the plains and forests of India. There are several regional strains of it, of which plain, transitional and hill varieties are three recognized types. Picea strain is found in hills at an altitude up to 7,000 ft, Pironi is distributed along the transition between altitudes of 3,000 to 4,000 ft. whereas, and Lighter indica is a plain strain found up to an altitude of 1,500 ft. It builds several parallel combs (about 30 cm across) in protected places like hollow of trees, caves, in rocks and in other such cavities. Due to their mild nature and average output of honey between 3 kg. to 5 kg. Per colony per year, they are amongst the best of the Indian variety to be hired in artificial conditions. *Apis mellifica* or European bee is very common all over the Europe. This bee is similar to *Apis indica* in its habitates. There are several varieties and strains of this bee amongst them the Italian variety is the best. It yields an average of 100 to 400 lbs. of honey per year per colony. Attempts to domesticate this been in India on large scale has yet not been proved to be a success.

The yield of honey from Indian bees is quite poor compared to their Italian or South African counter-parts. The South African yield of 100 kg. Per hive is about twelve times more than the Indian average of 4.5 kg. Per hive per year. Cross breeds have developed and experiments are going on at Palampur campus of the Punjab Agricultural University. The crosses between Indo- Italian swarms have yielded 51 kg. of honey per hive. But all these are in experimental conditions and at present we can only hope for a brighter future in the field of apiculture.

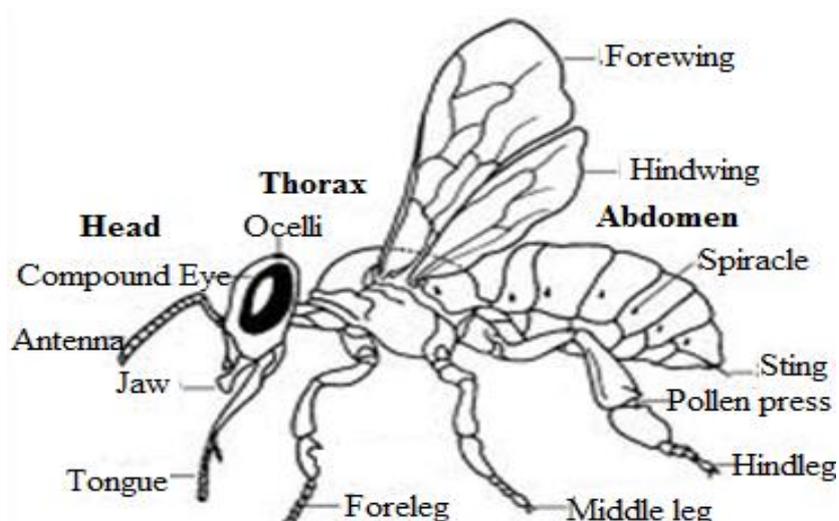

Fig.3.1 Anatomy of Honey bee

Habit and Habitat

Honey bees are highly organized social insects reported from all over the world. Although they are active throughout the year but in winter season they do little work and do not rear the brood. In spring seasons i.e. at the time of flowering they prepare a strong colony with honey rich combs. They exhibit polymorphism and good division of labor. The bee hives with thousands of individuals are observed hanging down from the branches of the trees and ceilings of houses. The workers communicate information's for the location of the food sources through the 'Waggle Dance', a phenomenon called as 'Language of the bees', by the eminent biologist Kari Von Frish. He has mentioned that the rate of dance is directly proportional to the distance of the food.

Life History

After mating the queen generally lays one egg in one brood cell. The eggs are pinkish colored, elongated with cylindrical body generally attached to the bottom of the cell. Larvae

emerge out from both the fertilized as well as unfertilized eggs. Thus, the larvae from the unfertilized eggs form the drones while the workers are developed from the larvae of the fertilized eggs. Amongst the larvae of the workers one is fed on the royal jelly, a special diet secreted by the young workers in the colony and becomes the queen of the colony. The royal jelly consists of digested honey and pollen, mixed with a glandular secretion into the mouth of the workers. After 5 days of feeding the cell is sealed and the larvae undergo pupation. It spins a thin silken cocoon and pupates completely. Emergence of the young ones takes place after three weeks and they get busy in the indoor duties for about 2 to 3 weeks. Later on they are sent for the outdoor duties. All the bees pass through a complete metamorphosis with the various changes in the life-cycle taking place within the comb.

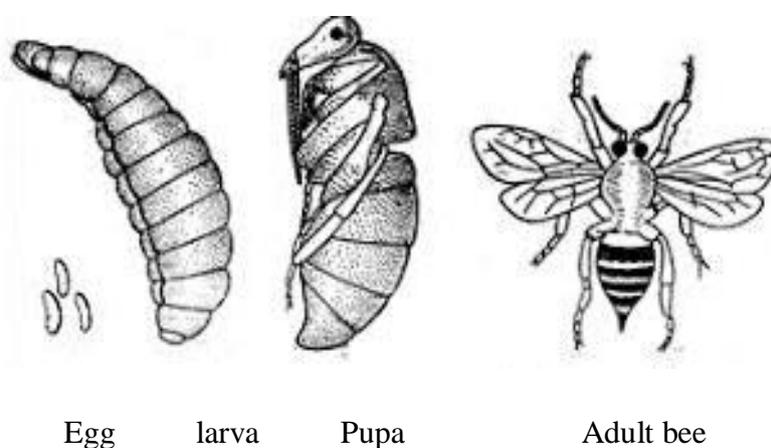

Fig 3.2 Life history of Apis Indica

Swarming: The process of leaving off the colony by the queen is termed as swarming. It happens towards the end of spring or early summer but the real cause of swarming is still not well known. In summers when plenty of food is available and the hive is overcrowded by the bees, the queen leaves the hive on a fine fore-noon with some old drones and workers and establishes a new colony at some other place. Now in the old hive a worker is given Royal Jelly and is converted into a new queen of the colony. This new empress of the colony never tolerates her successor, as a natural law in the hive, so she orders to kill the other sisters, if any, in the hive.

Supersedure: When the egg laying capacity of the old queen is lost or it suddenly dies, a new young and vigorous queen takes the position of the old queen and is called as supersedure.

Abscinding: The migration of the complete colony from one place to another takes place due to some unfavorable conditions of life, such as destruction of the comb by termites or wax-moths and scarcity of nectar producing flowers around the hive. This phenomenon is quite different from that of swarming.

3.4 MANAGEMENT OF BEES COLONIES

Social Organization of Honey Bee

A highly organized division of labour is found in the colony of honey bees. A good and well developed colony of bees had 40 to 50 thousand individuals consisting of 3 castes viz., Queen, drones and worker. The queen lays fertilized and unfertilized eggs both. From unfertilized eggs male bees emerge which are known as Drones whereas from the fertilized eggs worker bee is produced. The workers when feed on Royal jelly, develop into Queen.

Queen: It is a well-developed fertile female provided with immensely developed ovaries. Commonly one queen is found to be present in each hive and feeds on Royal Jelly. She is the queen in real sense as the Mother of the Colony, guarded by a number of attendants and never allotted any duty except egg laying. Egg laying is the sole function of the queen throughout her active life span. The queen is 15 to 20mm in length and can be easily distinguished by her long tapering abdomen, short legs and wings. Structurally she is unable to produce wax or honey or gather pollen nectar. By the combination of ovipositor-cum sting, a structure is developed which aids in egg laying. It is said that the queen gets mated only once in her life but in a single chance of mating, drone releases 2 crore sperms which are sufficient for the fertilization of the eggs at the time of egg laying by the female throughout her life span. In recent researches in U.S.A it has been reported that out of 110 queens only 55 mated twice before egg laying. It is also a fact that queen lays fertile and unfertile eggs both in accordance to her will but the factors governing such selective activity are still not know. One queen lays about 1,500 and 2,000 eggs in a day depending upon the seasonal variation and other ecological factors.

Queen

Drone

Worker

Fig. 3.3 Queen, Drone and Worker

Workers: Although the workers are the smallest of the three castes but they function as the main spring of the complicated machinery like honey bee colony. Like the queen, they are also produced from the fertile eggs laid by the queen and live in a chamber called as ‘WORKER CELL’. It takes 21 days in the development from the egg to the adult and the total life span of a worker is about 6 weeks. The workers are atrophid female which sacrifice themselves for the well-being of the colony. The total indoor and outdoor duties of the colony are performed by the workers only. That is why they are provided with some special structures for particular work.

- (1) Long proboscis for sucking the nectar.
- (2) Strong wings for fanning.
- (3) Pollen baskets for the collection of pollen.
- (4) Powerful string to defend the colony against any attack.
- (5) Wax gland for wax secretion.

The workers which are engaged in outdoor duties collect the nectar, pollen, gum and water which are received and stored properly by the house bees. The Indoor workers are further sub-grouped for specific duties. Some of them which are very sincere attend the queen while some others look after the nursery called as NURSERY BEE. Some produce wax for the formation of the new hive and are known as BUILDERS. The repairing of the comb is done by the REPAIRERS. The dead body and other impurities are removed from the hive by the CLEANERS. The fanning in the hive is performed by the wings of the FANNERS. Several other functions like honey storage and ripening are also done by the workers. The guard bee always watches at the gateway. It is said that up to half of their life period workers perform indoor duties and later on become engaged in outdoor duties.

Drone: The drone is the male member of the honey bee colony which fertilizes the queen so called as King of the colony. They take 24 days to develop from the egg to the adult stage. The sting and the wax glands are absent but in the males the reproductive organs are very well developed. They are reared from an unfertile egg in large DRONE CELLS. Drones are totally dependent on the workers and have been seen begging for honey from the workers. The sole duty of the drone is to fertilize the virgin queen. At the time of swarming the drone follows the queen, copulates and dies after copulation.

3.5 BEES ENEMIES & THEIR CONTROL

Enemies of the bees harm the colony in different ways so they have attracted considerable attention in the different region of the country. The wax moth *G.mellonella* & *A.grisella*, wasp (*vespa spp.* & *palarus sp.*) black ants *componotus compressus* and bees eaters etc, are the common enemies of the honey bees comb and honey.

Enemies of Honeybees:-

1. Wax Moth (*Galleria mellonella*):

It is one of the most important enemies of the bee colony causing serious damage particularly to weak colonies. The caterpillars live in the silken tunnels made by the bees, feed on the propolis, pollen, and wax in the combs. The presence of loose dislodged particles in the hive is the first symptom of attacks. When the infestation is serious, the comb is seen covered with silken webs with the numerous black faecal particles of the caterpillars. The insect can be controlled by frequent examination of hive, cleaning all the crevices and removing all debris.

2. Ants:

The black ants and red ants are dangerous enemies of the bee. They attack weak colonies and carry away the honey, pollen and the brood. By providing ant pans around the bases of the stand or oil bands over the stands ants can keep away.

3. Wasp:

It waits near the entrance of the hive; catches bees as they come out, macerate them for feeding the juice to its young. By reducing the width of the alighting board of the hive, the

wasps can be prevented from sitting near the entrance. The wax beetle, birds and death's head moth are also other enemies of honeybees.

3.6 EXTRACTION & PROCESSING OF HONEY

Selection of Bees for Apiculture:-

For running a good apiary, selection of honey bee is of much importance, so the following should be kept in mind at the time of selecting honey bees for apiculture:

- (1) Honey bees should be of gentle temperament.
- (2) Honey bees should have capability to construct strong colony.
- (3) It should have ability to protect from enemies.
- (4) Honey bee should have energetic and industrious workers.
- (5) Workers can suck juice from numerous varieties of plants.
- (6) Bees on the whole can produce more and more honey from its comb.
- (7) Bees can form their comb easily at any place.

The apiculture scientists engaged in genetics are trying to find out such cross races which would not be of ferocious nature but be a good honey producer in India; *Apis Indica* is the best bee for apiculture industries due to its gentle nature and having efficient and prolific workers.

METHODS OF BEE KEEPING:-

The ultimate aim of bee keeping is to get more and more honey in pure form. The old method commonly used by old apiculturists is very crude, cruel and of unplanned type. This old method is called as indigenous method.

Indigenous Method:-

1. Hive: Two types of hives are used in indigenous method of bee keeping e.g., wall or fixed hive and movable hive.

- (a) **Wall or fixed hive:** It is purely natural type of comb because the bees themselves prepare the hive at any space on the wall or trees. There is an opening on one side through which bees come out of the hive.

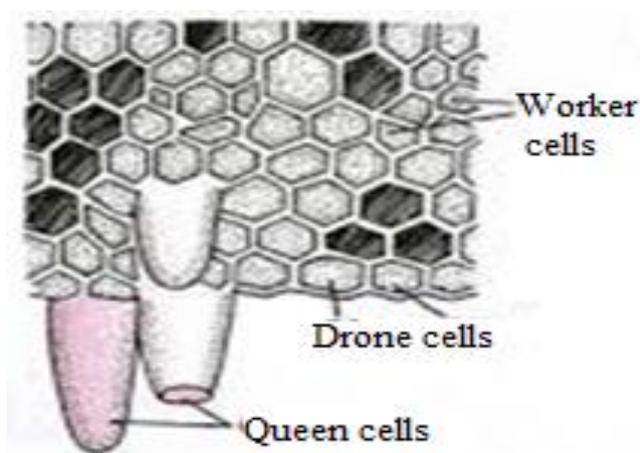

Fig.3.4 Hive of Apis Indica showing various cells

(b) Movable hive: It comprises of hollow wood logs, empty boxes and earthen pots etc. placed in varandas of houses. There exist two holes; one is for entrance and the other for exit of the bees. The swarmed bees usually come to the box on their own accord. Some bee keepers use to take the clusters of the swarms from a tree and keep them in the hive.

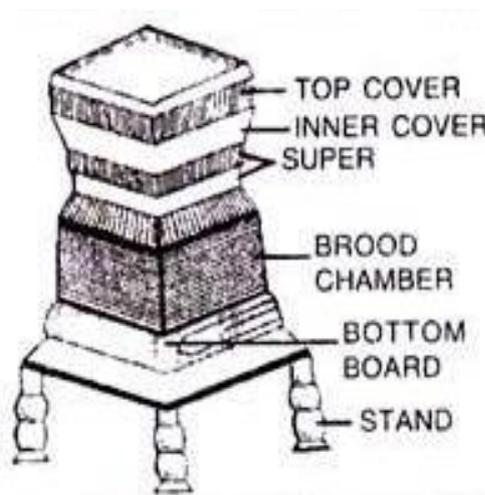

Fig.3.5 A Movable hive

2. Extractive of honey: For honey extraction, burning fire is brought near the bee hive at the night as a result of which bees are either killed or they escape off. Further the hive full of honey is being removed, cut into pieces and squeezed to get honey. Sometimes smoking is done so that the bees may escape from their hives.

3. Drawbacks of indigenous method: The indigenous method of bee keeping suffers from a number of drawbacks due to which it is not recommended by present day panel. These

drawbacks are: (i) Honey become impure because at the time of squeezing, the brood cells, pollen cells, honey cell and larvae are also extractes. (ii) The colony becomes weak due to killing of the eggs and the larvae at the time of squeezing. (iii) Formation of new hive by the escaped bees requires extra energy which affects the yield. (iv) The activities of the bees can be controlled. (v) The hivation of bees on the same place is only matter of chance. (vi) The honey robbers, like, rat, ant, wasp and monkeys may affect the hive easily. (vii) The race improvement programme may not be applied, so no possibility for the selection of the best is there. (viii) The hazards created by climatic factors cannot be controlled.

Modern Method of Apiculture

To overcome the drawbacks of indigenous method an advanced method based on scientific facts has been developed. It has opened a new era for the cottage industry in India and has also given an opportunity for lakhs of unemployed persons to keep them busy in this business. From this cottage industry programme the routine agricultural work may not suffer. First of all care was taken to improve the texture of the hives and during this race hive patterns were introduced in India. The Newton model with 7 to 10 frames (21×14.5 cm) in the brood chamber with a shallow super (21×6.5 cm sized frames) has been most popular in south, east and central India. Longstroth hive containing 10 frames (44.8×23 cm) has been used as a standard hive in Himachal Pradesh, Jammu and Kashmir and Punjab. In Uttar Pradesh another type of hive has been in use which was evolved at Jyolikote (Nainital) apiary and contained 8 frames (30×18 cm). After gaining experience from the above mentioned hives, Indian Standard Institute has standardized the hives of small and big sizes accommodating frames 21×14.5 cm and 31×20.4 cm respectively.

Now-a-days a typical type of movable hive is constructed which is capable of expansion or contraction according to the requirement of the place, season and climatic conditions.

Advantages of Modern Method

In the modern method of bee keeping there are several advantages which encourage the well planned bee keeping.

- (1) A proper watch on the activities of the bees can be had.
- (2) A strong colony can be developed by providing sugar, syrup, and pollen substances to honey bees.
- (3) Swarming of bees is checked by modern hive.

- (4) The same hive is used again and again so the workers pay their attention more for the honey and not for the hive formation.
- (5) Under adverse climatic conditions the hive can be transferred from one place to the other for the protection of the bees.
- (6) Comb can be protected from the enemies.
- (7) Pure honey in large quantity can be obtained.

Precautions: For the proper management of bee keeping programme following precautions should be taken.

- (1) The hive should not be kept more than half a mile away from the place from where the bees have to collect the nectar and the pollen.
- (2) People must know about the bee keeper for proper contact.
- (3) The boxes must be kept under shade at cool places.
- (4) Industry should be near the road for proper transport facilities.
- (5) Fresh water reservoir should be near the hive.
- (6) Good flora for the collection of pollen and nectar should be there.

Products of Bee Keeping

The chief products of bee keeping industry are

1. Honey and
2. Bee wax.

Honey

It is truly an insect product of high nutritive value. The food value of honey may be estimated by the presence of about 80% sugar in it.

Production of honey: One should not be confused that honey is a direct plant product because the nectar, pollen and cane-sugar bearing secretions of flowers are ingested by honey bees, get mixed with the saliva and undergo certain chemical changes due to enzyme action. At this stage cane-sugar (sucrose) is converted into invert sugars i.e., dextrose and levulose. At this very time some ingredients of bees are also added to the mixture and reduce the water content. The whole mixture is then collected in the honey sac (crop) until the honey reaches the hive. As the honey bee reaches the hive this compound is regurgitated in the hive cell and

is known as the honey. Now honey is concentrated by a strong current of air produced by the rapid beating of worker's wings, crawling over the cells.

3.7 ROLE OF HONEY BEES IN POLLINATION

Since the **honey bee** is the most important insect that transfers pollen between flowers and between plants, the word "**pollination**" is often used to describe the service of providing **bees** to **pollinate** crop plants. Pollination is the transfer of pollen grains, the male sex cells of a flower, from the anther where they are produced to the receptive surface, or stigma, of the female organ of a flower. Since the honey bee is the most important insect that transfers pollen between flowers and between plants, the word "pollination" is often used to describe the service of providing bees to pollinate crop plants. This service is now more important than ever in the Midwest because the acreage of insect pollinated crops is large as compared with the number of all kinds of bees (honey bees, humble bees, and solitary bees) that are available to provide pollination. In many states the estimated number of colonies (hives) of bees has dropped drastically in recent years. For example, in Illinois the estimated number of hives dropped from 101,000 in 1964 to 46,000 in 1984. These two figures are probably much more accurate than some of the older, larger estimates that may have reflected state pride more than reality. Because of the reduction in numbers of bees, growers in any state can no longer assume that there are sufficient numbers of bees nearby to produce the best possible crop from insect pollinated plants.

Fig.3.6 Honey bee hive placed in Apple Orchard

Honey bees are good pollinators for many reasons. Their hairy bodies trap pollen and carry it between flowers. The bees require large quantities of nectar and pollen to rear their young, and they visit flowers regularly in large numbers to obtain these foods. In doing so, they

concentrate on one species of plant at a time and serve as good pollinators for this reason. Their body size enables them to pollinate flowers of many different shapes and sizes. The pollination potential of the bees is increased because they can be managed to develop high populations. The number of colonies can also be increased as needed and the colonies can be moved to the most desirable location for pollination purposes.

Hive

The house of honey bees is termed as hive or comb. It consists of hexagonal cells made up of wax secreted by the worker's abdomen. These hives are hanging vertically from rock, building or branches of trees. Each hive has thousands of hexagonal thin walled fragile cells arranged in two opposite rows on a common base. The resins and gums secreted from the plants are used for the repairing of the hives. The young stages are generally occupying the lower and central cells in the hive which are the 'BROOD CELLS'. In *A. dorsata* brood cells are similar in shape and size but in other species brood cells are of three type's viz., WORKER CELL for workers, DRONE CELL for drones and QUEEN CELL for the queen. Queen cell cannot be used again while the rest are used a number of times. There are no special cells for lodging the adults which generally keep clustering or moving about on the surface of the comb. The cells are mainly intended for

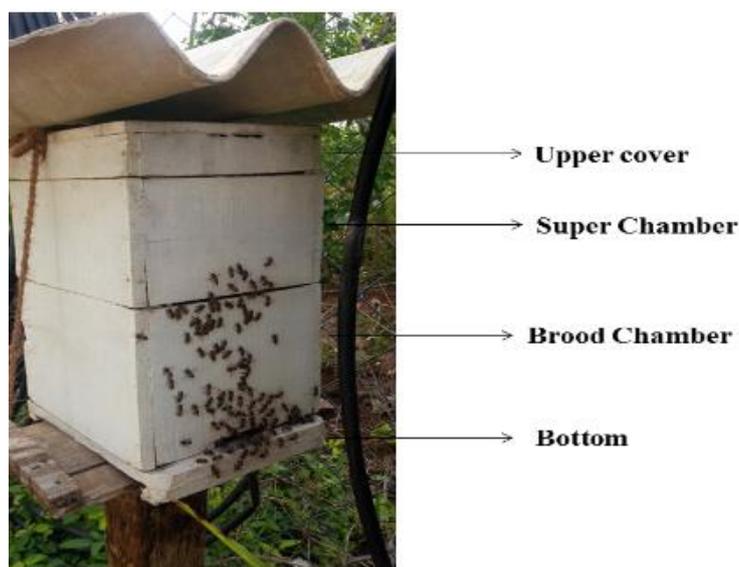

Fig.3.7 Hive of bee

the storage of honey and pollen especially in the upper portion of the comb while those in lower part are for brood rearing.

Flora for apiculture

Although honey bees can collect nectar and pollen from quite a long distance but the flora for apiculture is also important. The flora may be of wild or cultivated type. The more nectar yielding plants are neem, jamun, soapnutect.. The other plants like maize, rose and sorghum are good sources of pollen. Some plants like plum, cherry, apple, sheesham, coconut, guava, mustard etc., are good sources for nectar and pollen both.

Chemical composition of honey:

Honey is sugar rich compound having the following constituents:

(1) Levulose	-38.9%
(2) Dextrose	-21.28%
(3) Maltose & other sugars	-8.81%
(4) Enzymes & pigments	-221%
(5) Ash	-1.0%
(6) Water	-17.20%

Storage of honey: After long duration in the stored condition, the honey may be granulated and fermented.

- (a) *Granulaiton of honey:* The stored honey becomes granular after long duration. Such type of granulation property is the best evidence of pure honey. It is considered that 10 parts of dextrose combine with one part of water, hence forms crystals. Due to less solubility levulose is not crystallized and gives cloudy appearance. Crystallization is mainly accelerated by the presence of minute air bubbles, colloids and pollens.
- (b) *Fermentation of honey:* After crystallization honey is subjected to fermentaition. Due to crystallization of dextrose 9% moisture is released, which dilutes the remaining levulose of the honey and the action of yeasts present in air, flowers and soils takes place on levulose and dextrose resulting in the fermentation of honey.

Economic Importance of honey: Honey is used by human beings in different ways of which the most important is as food and medicine.

- (a) *Food value:* It is estimated that 200gm of honey provides as much nourishment as 11.5 liter of milk of 1.6kg cream or 330gm meat. 2.1gm of honey provide as much as 67K. cal of energy. Its sugars, minerals, vitamins and other vital elements are readily absorbed by the systems. Honey may be taken by healthy men as well as those who are ill. It can be taken at any time any season and by persons of all ages even those just born. It is used in the preparation of candles, cakes and bread. In illness it is preferred over milk because more than half of the body energy is provided burning of dextrose.
- (b) *Medicinal value:* Honey is mildly laxative, antiseptic and sedative, generally used in Ayurvedic and Unani systems of medicine. It is quite helpful in building up of the hemoglobin of the blood and also used as preventive against cough, cold and fever, as blood purifier and as a curative for ulcers on tongue and alimentary canal. Its regular use is recommended after severe cases of heart attack for malnutrition, indigestion and diabetes. It is also found that typhoid germs are killed by honey within 48 hours, those of branchio-pneumonia in 4 days and of dysentery in 50 hours.
- (c) *Other uses:* Other than food and medicine, honey is used in numerous ways. It is used in the preparation of bread, cake and biscuits. It enhances their preserving quality. Much amount of honey goes in making alcoholic drinks. In poultry and fishing industries honey is widely used. In laboratory, honey is used to stimulate the growth of plants, the bacterial culture, and inoculation of seeds of cloves, in insect diet and in the preparation of poison baits for fruit flies.

3.5 SUMMARY

Honey bees are highly organized social insects reported from all over the world. Although they are active throughout the year but in winter season they do little work and do not rear the brood. In spring seasons i.e. at the time of flowering they prepare a strong colony with honey rich combs. They exhibit polymorphism and good division of labor. Beeswax is a very useful by-product of bee keeping industry. It is yellowish to grayish brown in colour and insoluble in water but completely soluble in ether. Commonly it is a wrong impression to suppose that honey bees convert the pollen into beeswax because beeswax is also a natural secretion of the worker bees and is poured out in thin delicate scales of flakes. The various beeswaxes differ only due to change in the proportions of these constituents. Large quantities of beeswax produced and exported, come from *Apis dorsata* bees, Indian Standard Institutions have fixed standards for pure beeswax in order to facilitate its export. Beeswax is used in the

manufacture of cosmetics, for Catholic churches, face cream, paints, ointments, insulators, plastic works, polishes, carbon paper and many other lubricants. It is also used in the laboratory for microtomy with the common wax for block preparation of tissues.

3.7 SELF ASSESSMENT QUESTION

- Give an account of the social organization and life history of the honey bees?
- Describe the method of Bees Keeping?
- Explain the bee's enemies?
- Give the short account of the species of honey bees?
- What is beeswax?
- Give the economic importance of honey bees?

UNIT-4 LAC CULTURE

CONTENT

4.1- Objectives

4.2-Introduction

4.3 Different kinds of Lac producing Insect

4.3. 1 Host Plant

4.3.2 Life cycle of Lac insect

4.6-Terminal question

4.7-References

4.1 OBJECTIVES

The study of Different kinds of Lac producing Insect and Host Plant and discuss the Life cycle of Lac insect and Disease of Lac insect.

4.2 INTRODUCTION

Lac is the scarlet resinous secretion of a number of species of lac insects, of which the most commonly cultivated species is *Kerria lacca*. Cultivation begins when a farmer gets a stick (broodlac) that contains eggs ready to hatch and ties it to the tree to be infested. Thousands of lac insects colonize the branches of the host trees and secrete the resinous pigment. The coated branches of the host trees are cut and harvested as sticklac. The harvested sticklac is crushed and sieved to remove impurities. The sieved material is then repeatedly washed to remove insect parts and other soluble material. The resulting product is known as seedlac. The prefix seed refers to its pellet shape. Seedlac which still contains 3–5% impurities is processed into shellac by heat treatment or solvent extraction.

4.3 DIFFERENT KINDS OF LAC PRODUCING INSECT

Lac insect (*Tachardialacca*) previously known as *Laci ferlacca* is a minute, resinous, crawling scale-insect which inserts its beak into plant tissues, sucks juices, grows and secretes lac from the hind end of the body. Its own body ultimately gets covered with lac in the 'Cell'. lac is actually secreted for its protection and not for the food of the insect. The commercial lac is produced in large quantities by female as a protective covering of its body which is injurious to the host plants.

Classification

Lac----- Insect (lakh ka-kira)

Phylum -----Arthropoda

Class -----Insecta

Order-----Hemiptera

Genus -----Tachardia

Species -----lacca

Male: male is red in colour and 1.2 to 1.5 mm in length. It secretes bright creamy lac. It has reduced eyes and ten segmented antennae. The mouth-parts are of piercing and sucking type.

Thorax bears three pairs of legs and one pair of hyaline wings. The abdomen is eight segmented and terminates into a short, chitinous prominent genital sheath containing penis. On either side of this genital sheath a white elongated caudal seta is found.

Female: Female is larger than males and measures about 4 to 5 mm in length. The pyriform body of the female is enclosed in a resinous cell. The head, thorax and abdomen are not clearly distinct. The mouth-parts are of piecing and sucking type. The antennae are clearly visible and degenerated. The posterior end of the body has a median and two lateral processes. The legs are in degenerated form.

4.3.1 HOST PLANT

The lac insects have more than one host plant. The selection of suitable host plant for the cultivation of lac is of much importance. To establish the lac industry one should know well about the topographic and climatic conditions for the growth of host plants suitable for the particular region. Brun (1958) has mentioned that 113 varieties of host plants are found in the geographical Indian regions including Pakistan and Myanmar. Out of these 113 host plants only 14 are very common in India which is as follows:

- Kusum – *Schleichera oleosa*
- Babul – *Acacia nilotica*
- Ber – *Zizphus mauritianas*
- Palas – *Butea monosperma*
- Ghont- *Zizphus xylopyra*
- Khair – *Acacia catechu*
- Peepal – *Ficus religiosa*
- Gular – *F. glomeratu*
- Pakapi – *F. virens*
- Putkal- *F. globella*
- Mango- *Mangifera indica*
- Sal – *Shorea robusta*
- Shisham- *Dalbergia sisso*
- Fig- *Ficus carica*

The quality of lac is directly related with the quality of host plant. So far, no artificial product has been able to replace the lac. Khair, Kusum and Babul give better quality of lac when

sown directly in the field. But Palas, Ber and Ghont give good crop when they are first sown in nursery and then transplanted to the lac growing field. Palas and Ber produce a particular type of lac which is called as 'Kusumi lac'.

CULTIVATION OF LAC:-

Lac cultivation is a complicated process, so the cultivators should know well about the inoculation, swarming period and harvesting of lac.

Inoculation:-

The first procedure in the lac cultivation is the inoculation of lac insect. Inoculation is the process by which young one gets associated properly with the host plant. Inoculation is of two types:

1. **Natural inoculation:** The inoculation taking place in natural way is very simple and common process during which the swarmed nymphs infect the same host plant again and start to suck the juices from the twigs. The natural incubation of swarmed nymphs has some drawbacks which are as follows:
 - (a) **Incomplete nutrition:** Lac insects with their piercing and sucking mouth-parts, pierce into succulent twigs and suck the cell sap of the same host plant for nutrition. If the cell sap of the same host plant is further sucked out by the swarmed nymphs of the second crop continuously, the growth of the host plant would be retarded. In this way lac insect may not be able to get enough nutrients from the same host plant. The lac insects due to lack of sufficient nutrients lose their proper development, thereby affecting the production of lac also.
 - (b) **Irregular inoculation:** During the natural inoculation it is not sure that uniform sequence of inoculation takes place. If inoculation is not of continuous fashion, a regular crop of lac may not be obtained.
 - (c) **Unfavorable climatic conditions:** At the time of swarming a number of factors like high intensity of sunlight, heavy rainfall, flow of wind etc. affect the proper inoculation of nymphs. These natural environmental factors may also affect the host plant at the same time and may cause a gap of inoculation resulting in irregularity of the lac crop.
2. **Artificial inoculation:** The main idea behind the artificial method of inoculation is to check all possible drawbacks of natural inoculation.

In this method first of all host plant should be pruned in January or June. The twigs bearing insect nymphs which are about to swarm or just before swarming are cut in sizes ranging between 20 to 30cm in length. Then the cut pieces of these twigs are tied to fresh trees in such a way that each stick touches the tender branch of the tree at several places which form bridges for the migration of the nymphs. After swarming, these twigs should be removed and separated from the host plant. The following precautions should be taken in artificial inoculation:

- (1) One must ensure that the twigs, which are going to be tied on fresh host plant, are having good number of nymphs or eggs. It is also possible that from many of the twigs nymphs have swarmed out, thus inoculation would prove unsuccessful.
- (2) The twigs provided with eggs or nymphs should be without any parasite and predator.
- (3) The eggs or nymphs present on the twigs should be healthy and about to swarm so that one has not to wait for longer period and thus save time.
- (4) For the uniformity of inoculation, 3 to 4 twigs should be utilized.
- (5) Host plants should be changed from time to time for the proper nutrition of the nymphs.

These insects are very small and if they move to a long distance there are chances of mortality of the nymphs. Due to maximum contact of twigs, swarming nymphs have not to move for long distance and find suitable places to establish on the host plant.

Inoculation Period

In India two types of crops viz., Rangini and Kusumi are grown in a year. The Rangini crop is of two types called as Kartiki and Baisakhi crop which produce Kartiki and Baisakhi lac respectively. The Kusumi crop is also of two types viz., Agahani and Jethi which produce Agahani and Jethi lac respectively.

Thus, the inoculation periods of all the four types of crops are different. The inoculations of Kartiki, Baisakhi, Agahani and Jethi crops are recommended in months of June to July, October to November, July and January to February respectively. But if continuously four crops are taken, the plant would not get any rest which may cause less production of lac.

Swarming

It is very important phase in the life history of lac insect. We should have accurate knowledge about the actual date of the swarming. At the time of swarming, the upper surface has yellow

spot on the anal region. At this stage muscle contracts and insect gets detached from the place of attachment. Thus, it leaves a hollow cavity which later on gets covered with wax also. When these eggs are to be hatched out they become orange colored. It is an indication that swarming has taken place. Thus, by trials and learning methods i.e., by practice one could know about the exact date of swarming by looking at the colour of the eggs.

Harvesting of Lac

The process of collection of ready lac from host tree is known as harvesting. In common practice the harvesting is of two types.

1. **Immature harvesting:** The harvesting of the lac before swarming is called as immature type of harvesting and the lac thus obtained is known as 'ARI LAC'.
2. **Mature harvesting:** The collection of crop after the swarming is called as mature harvesting and the lac obtained is known as 'MATURE LAC'. The harvesting of lac before the swarming has some drawbacks because the lac insects may be damaged at the time of harvesting which would affect the population of lac insects and ultimately result in great economic loss to the cultivators. But in case of palas lac (Rangini lac) it is found that Ari lac gives better production. Therefore, Ari lac harvesting is recommended in case of palas only. In all other cases immature harvesting should be discouraged. It is also found that in cold areas mature crop yields quality of lac.

Harvesting period:

The harvesting periods of different crops are quite different in accordance with the inoculation of crops. kartiki crop is harvested in October to November whereas, Baisakhi crop in May and June. The other crops like Agahani and jethi are harvested in January to February and June to July respectively.

Composition of Lac

Lac is a complex substance having large amount of resins, together with sugar, water and other alkaline substance. The percentage of various constituents is as given below.

(1) Resin	- 68 to 90%
(2) Dye	-2 to 10%
(3) Wax	-6%
(4) Albuminous matter	-5 to 10%
(5) Mineral matter	-3 to 7% and
(6) Water	-3%

Properties of Lac

- (1) Lac is not soluble in water but easily soluble in alcohol. This property of lac has great value for insulation of electrical connections.
- (2) Lac is easily fusible on heating.
- (3) Lac has adhesive quality.
- (4) It has binding property when mixed with alcohol.
- (5) lac is also soluble in weak alkali like ammonia.
- (6) Lac is a bad conductor of heat.

ENEMIES OF LAC CULTIVATION

Lac cultivation is destroyed by biotic and abiotic factors:

1. **A biotic enemies:** These are high intensity of light, high temperature, high humidity, heavy rainfall and flow of wind.
2. **Biotic enemies:** The main biotic enemies of lac cultivation are mammals and insects, Krishnaswami et al. (1957,59), and Gepulpure et al.(1963), have reported that squirrel, rats and monkeys cause great damage to the lac crop.
The insects are very powerful enemies of lac crop. Annual loss due to the insect enemies is to the tune of about four lakh maunds. The insects damage the crops in different ways.
3. **Parasites:** The lac insects are parasitized by eight species of chalcidoid parasites like, *Parenthrodryinusclavicornis*, *Erencyrtusdewitzil*, *Tachardi-aephagustachardiae*, *Tachardiaephagustachardiae* var. *somervilli*, *Eupelmustachardiae*, *Coccophagustschirchil*, *Marietta javensis* and *Tetrastichuspurpureus*. These parasites lay their eggs into lac insects and parasitised 4.8 to 9.9 % of lac insects per year and 1/3 of the parasitised cells are males. Thus, it may be concluded that parasitization is not a major cause of the damage to the lac cultivation.
4. **Predators:** Predators cause very severe damage to lac cultivation and 35% of the lac cells are damaged by two predators viz., *Eublemmaamabilis* Moore (Lepidoptera: Noctuidae) and *Holocerapulverea* Meyr (Lepidoptera: Blastobasidae). Female lays eggs near encrusted twigs from larva emerge and feed on lac insects.

4.3.2 LIFE CYCLE OF LAC INSECT

Each mature female just after fertilization lays about 200 to 500 eggs in a cell in which she is enclosed. The oviposition takes place into the incubating chamber which is formed by the

contraction of the body of the female in forward direction inside the lac cell. The eggs are laid in the months of October and November. After six weeks of lying, the eggs are hatched into first instar nymphs in the month of November and December. When nymphs emerge they are in quite large number. This mass emergence of the nymphs is known as 'SWARMING'

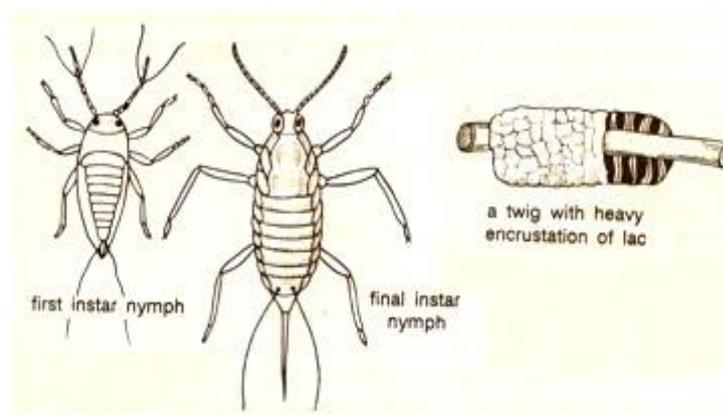

Fig 4.1 Life cycle of Lac Insect

Nymph: At the time of emergence the nymphs are about 0.5 mm in length, red coloured and boat-shaped. The head bears paired antennae, ocelli and ventrally situated piercing and sucking type of mouth-parts. The mouth-parts are provided with proboscis. The tree segmented well developed thorax contains two pairs of spiracles and only one pair of walking legs. The abdomen contains two pairs of legs and terminates into a pair of long caudal setae. The active nymphs can crawl to a considerable distance so, just after emergence they start moving in search of food and reach their host plants, preferably on young and succulent shoots because the young nymphs are unable to settle very close to each other on the twig of the host plant which further collapses completely and forms a continuous covering even on the lower surface of the twig. The number of nymphs that settle per square inch area is about 150 to 200. Settled nymphs suck the sap from the twig of the host plant and start to secrete the resinous substance by special dermal glands which are located all over the body. As the resinous secretion comes in contact with air, it soon becomes hard and forms a coating over the body of nymph and is called as 'CELL'. Within this cell various life processes like growth of the nymph, morphological changes and lac secretion take place.

The male 'CELL' is elongated and cigar-shaped having two holes i.e., anterior and posterior. From the posterior hole which is covered by a flap or operculum, the male insect comes out by pushing open the operculum. After six to eight weeks of stationary life the nymphs are metamorphosed as a result of which some (30%) active winged males and maximum (70%) emerge in the form of females which are wingless. The females get fixed on the host plant in resinous mass.

Due to short life period males do not take major part in the secretion of lac but female secretes lac throughout her life and its life span is longer than males. Major quantity of lac is secreted from females. The life cycle period depends mainly on ecological factors of the region.

Economic Importance

In 19th century lac dye was in more use than lac resin. Presently due to availability of a better and cheaper annaline dyes the use of lac as a dye has been discarded. The manifest uses of lac is one of the Nature's standing gifts. The various used to which it is put are:

- (1) It is utilized in the preparation of gramophone records. Previously this industry utilized major part of the lac produced annually. But now days to a great extent plastic is being used in this trade.
- (2) It is of utility to Jewellers and Goldsmiths who use lac a filling material in the hollows in gold ornaments like bracelets, armlets, bangles and necklaces etc.
- (3) It is an essential gradient used extensively for making polishes, paints and varnishes for finishing wooden as well as metal furnitures and doors etc.
- (4) It is utilized for the preparation of toys, buttons, in pottery and artificial leather.
- (5) It is used in the manufacture of photographic material, lithographic ink and for stiffening felt and hat materials.
- (6) It is used as an insulating material for electrical goods.

4.6 TERMINAL QUESTION

1. Discuss on the host plant of Lac Insect?
2. Describe the natural inoculation of Lac Insect
3. Give a detail account of the life history of Lac Insect?
4. Explain the swarming of the Lac Insect?
5. Explain the Cultivation of the Lac Insect

5.1 OBJECTIVES

1. The objective of this chapter is to understand the poultry farming.
2. To understand their food & feeding habits.
3. A detailed study of breeds of fowl.
4. To understand the disease caused to them.
5. Understanding the economic importance of poultry & poultry products.

5.2 INTRODUCTION

Fowls are widely distributed as domesticated animal since times immemorial. In twentieth century poultry keeping has become an important small scale industry due to modern need for palatable and nutritive food which it provides in the form of eggs as well as adult animals. The storage and transport facilities also have helped to a great extent in its becoming popular as a trade. This naturally has attracted the attention of the people at large and the scientists in particulars necessitating new researches on breeding, hatching and rearing of fowls. India is the native place of the wild jungle fowl but little attention has been paid for developing poultry industry in comparison to other countries. In country like India, the increased egg consumption is essential for the proper nutrition of human beings. The researches carried out at the Imperial Veterinary Research Institute, Izatnagar have demonstrated the high biological value of eggs and recommended the consumption of eggs in supplementing the defective human diets. For the successful management of poultry industry one should have detailed idea about the poultry ground, habitat of fowl breeds, breeding and rearing of chickens. Though there are several Government Poultry Farms in India but the poultry is almost entirely in the hands of poor persons, thus eggs available are of small size.

5.3 HABITAT OF FOWL

1. Soil. For fowls, soil should be sandy, gravelly and abounding in kunkar alongwith good amount of lime. The stony soil is not suitable for fowls because stones cause damage to feet of the fowl. The heavy soil with high percentage of moisture is harmful. The marshy, dirty and drained grounds are fatal to the animals.

2. Shelter. The poultry should be protected from the cold winds and heavy rains. They should not be allowed to walk in water.

3. Shade. The poultry should be well protected from hot sun and hot wind in summer season, so the site for the poultry ground should be such as to have a number of shrubs and trees. In summer season the west side of the poultry house should be closed in the day time otherwise they will die due to westerly wind. The places where trees are not found, a shed of 10 to 15 square feet should be made with bamboo and straw. The shed should be kept 3 feet above the ground surface with the help of bamboo posts. The ground where such shades are not possible, it may be constructed with metal and raised 2 feet from the ground on stone pillars. The ground beneath the shed should be raised about 3 inches from general surface for good drainage.

Fowl-House

Fowls can be reared in the hills of India without houses but in plains the specially constructed houses are essential for fresh and cool air in the early morning and evening. One adult fowl needs twenty five cubic feet of space. A house of 6 x 5 x 5 feet has sufficient accommodation for six fowls. An open shed or verandah must be attached to this house as a run way to the fowls for exercise. It is recommended that for six fowls a run of 40 x 30 feet is sufficient.

The fowl house may be either of wood or brick or metalled but the house of 'all metal' is best. The outdoor of houses must be towards south. It is advisable to construct a number of small houses rather than a single large one. The roof of poultry houses should be of either corrugated iron sheets, thatch, or wood. For the proper ventilation, the south side of the house should be enclosed with half inch mesh wire netting and other 3 sides have openings (12" x 6") and covered with wire-netting. The door of the house should be made up of an angle iron frame covered with mesh wire netting. The floor of the house should be pucca cemented and covered with coarse sand or dry earth sprayed with kerosene oil or phenyl. The sand layer must be changed after one month. The tick-proof perches of strong wood (3" in width) should be placed inside the house above 1.5 feet from the ground running parallel at 1.5 feet from the wall. The laying nets made up of 9 inch earthen gumlas (1.5 feet diameter, 9 inch depth), provided with dry ashes, sand or earth, should be kept in the corners of the poultry house for egg laying. A small gumla filled with old lime and mortar and the other gumla filled with coarse shell grits should be placed in the shed to supply the necessary grit and lime essential for the formation of egg shell. Light is also essential for the well-being of poultry, so these houses should always be constructed where natural light is possible without which fowls will die due to cold. Near the shed door or in the yard, a vessel filled with clean and fresh water should also be placed. Care should be taken against sun-warmed water which

causes cholera in the fowls. The house and shed should be cleaned daily and water should be changed twice a day. All wood work must be cleaned and painted with a mixture of tar and kerosene oil. The fowl house must be rat-proof because they destroy the eggs of chickens, and carry diseases into the fowl house. The broken glass should be spread on the floor under the bricks to make a pucca floor because rats can not burrow due to pieces of glass. Other enemy is snake which enters into the fowl-houses through the holes made by rats. Fowls also attack small snakes, kill and eat them but if snakes are cobra, krait or russel's viper the fowls are killed due to snake biting. One way to check the rats and snakes is to fill up the holes of poultry house regularly.

Food and Feeding of Fowls

The quality and balanced quantity of food material are the back-bones of poultry. The oats, peas, grams and beans are good food for fowls. The rice and Indian-corn (makka) are not proper food for the birds. The skimmed-milk, butter-milk and curds, mixed with ground wheat and barley, are of good nutritive value for them. The skimmed-milk is highly nutritive for young chicks' and should be given in clean vessels. The boiled potato, mixed with equal part of wheatbran, should be given for the fattening of fowls. Some animal foods like ground fresh bones and meat are also good for the health of fowls. The green food as fresh tender grass, garlic, lettuce, onions are essential part of food and should be given uncooked. The mustard seed, hemp seed and linseed should be given after some interval during cold season, rain and at the time of moulting.

Poultry keeper should have good idea about the amount of food allowed to the fowls at different stages of the life span, type of breeds and area of yards at poultry farms. The best diet recommended by Mr. A.J. Macdonald, ex-Poultry Research Officer, Indian Veterinary Research Institute, Izatnagar, U.P. is given below.

Maize meal	20 parts
Ground oat	20 parts
Wheat bran	40 parts
Earthnut meal	20 parts
Common salt	1 part

A good amount of green food and calcium should also be given with the above food. Too much grain feeding to fowls is very much harmful to them.

5.4 BREEDS OF FOWLS

The whole poultry industry is centred round the fowls so the selection of good breed of birds for particular area is essential. The origin and evolution of various breeds and their varieties are due to selective breeding for producing the fowl of different shape, size, colour, comb structure, ear lobe's etc. Domestic fowls may *be* categorised into two groups like Desi or the indigenous and the exotic or the improved.

Desi Breeds (Indigenous Breed)

The term desi is used to include all indigenous fowls exhibiting great variations in their shape, size and colour which, even if they have local names or pronounced characteristics e.g., Tennis, Naked-neck, Chittagong, Punjab brown, Aseel, Ghagus, Lolab, Titre, Kashmir faverolla, Bursa, Danki, Tellicherry, Kala hasti, Karaknath etc., are pure breed of fowl. The desi hen is, however, the best mother, as a rule, and makes an ideal sitter. She is also known to be very vigilant and a good forager. The pure desi breeds are Assel, Chittagong, and Ghagus.

Aseel

Aseel, means real or true, is the name given to an indigenous breed, because of its endurance, power and fighting qualities. The word Aseel is probably misnomer of the word 'Asli'. The original Aseel is a medium-sized aggressive bird commonly known as the Reza or the Tikra. The remarkable endurance of an Aseel even during the most critical stages of the fight is proverbial, because it fights to the last and prefers going down fighting to withdrawing. Pure specimens of this breed are now rare and are available with some fanciers in parts of Andhra Pradesh, Karnataka and Uttar Pradesh. Several varieties, mostly crosses between Aseel and local fowls are known in other parts *viz.*, Nhurie (white), Hyderabad peela (red), Yakhud (Black and red), Dhummar (blue dust), Teekar (Brown black), 'Zava (laced), Patteda (single combed) etc. Aseel is one of the best table birds as the meat is, delicious and flavoured. Because of its poor growth and low fertility, this breed cannot be bred on commercial scales as table bird.

Chittagong or Malay.

It is a native of Malay Peninsula and bred in Chittagong (Bangladesh) and is found in some parts of eastern India. The colour of this bird is white with splash of golden markings on the wing. This bird grows faster and is ideal for table purposes as its flesh is excellent.

Ghagus.

It is a peculiar Indian breed resembling the Faverolle in appearance but having feathers on the legs. It is a big and hardy breed found in Andhra Pradesh and Karnataka. Ghagus is a good table bird. The hen is a fair layer, good sitter and real mother.

BuStra

It is a minor breed of desi class found in small numbers in Gujarat and Maharashtra particularly around Mumbai. The birds have body conformation typical of layers, and are majestic, alert, deep bodied and light-feathered. The hen of this breed is poor layer.

Exotic Breeds

The term 'Improved' is applied generally to the exotic and comparatively modern breeds of Chickens imported into this country, where they are bred and acclimatised to the local conditions. The exotic breeds of poultry were introduced in India by early European residents such as missionaries, planters and civil servants. The exotic breeds have become quite popular here. According to the standard classification 'Chickens' are grouped into many classes which are further subdivided into about fifty breeds. Each breed has several varieties which differ from one another.

American Class

Polymouth Rock.

It is one of the most popular breeds of USA as it can attain good size with excellent flesh. It has fair egg laying capability. Six varieties of this breed have been reported of which Barred Polymouth Rock Cocks like those of the Rhode Island-Red, are good for upgrading the ordinary village or desi hens. Other varieties of Polymouth Rock breed are the white, Buff, Silver-pencilled, Partridge, Columbian and Blue. The white variety of this breed has been proved to be profitable as it has good capacity for egg and broiler production. The standard weight of this breed is cock-5.5 Kg, hen-4.5 Kg, cockered-5 Kg and pullet-4 Kg.

Wyandotte

It has a rounded body set close to the ground. Like Polymouth Rock, it is good breed for general purposes. It is very well adapted for flesh production and can lay good number of eggs of standard quality. The different varieties of this breed are white, silver-laced, Buff,

Partridge, Golden-laced, Silver-pencilled, Columbian and Black. The standard weight of this breed is cock-5 Kg, hen-4 Kg, cockered-4.5 Kg and pullet-3.5 Kg.

Rhode Island Red

It is one of the most popular breed of fowl in India with good quality of flesh, and the hens are very good layers. This breed is hardiest of all breeds which can survive well in varying climatic conditions. The flocks of this breeds are kept in government poultry farms and by commercial poultry keepers. The chickens grow quickly, are easy to rear and well suited for wet and heavy rainfall regions. There are two varieties of the Rhode Island Reds : the single comb and the Rose-comb which are otherwise identical. The single comb variety is more, popular of the two. The standard weight of this breed is cock-5 Kg, hen-3 Kg, cockered-4 Kg and pullet-2.5 Kg.

New Hampshire.

The New Hampshire is a relatively recent Island Red stock. Because of its unusual hardiness, it has gained great popularity in India. Its popularity is also due to its rapid growth, early maturity, fertility, hatchability and good laying capacity. The standard weights are the same as those of the Rhode Island Red.

Asiatic Class

The important members of this class are Brahma, Cochin and Langshan. They are not of any special value for their flesh but these breeds together with those of the Mediterranean class have formed the centre for the progressive development of new breeds and varieties. Fowls of this class mature slowly, are poor foragers and persistent sitters.

Brahma

The earliest Brahma is said to have come from India in the Brahmaputra area, where the fowls of original type, commonly known as 'Grey Chittagongs' are still to be found. This breed is massive in appearance and is one of the largest domesticated chickens. The standard weights of this breed is cock-6.5 Kg, hen-4.5 Kg, cockered-5 Kg and pullet-3.5 Kg.

Cochin.

This breed hails originally from the Shanghai district in China and was called as the Shanghai fowl. The breed may be Buff, White, Black or Partridge. Its outstanding characteristics are a massive appearance. and well feathered shanks. The feather is long and profuse, which makes the bird appear larger than it really is.

Langshan

This has its origin in the Langshan district of China. As compared with Brahma and Cochin, the Langshan has a shorter but deeper body. It is graceful bird with well proportioned body and with a single comb. The standard weight of this breed is : Cock-5 Kg, hen-4 Kg, cockerel-4.5 Kg and pullet-3 Kg. This class comprises of six breeds like, Sussex Orpington, Australorp, Cornis, Dorking and Red cap.

I. Sussex.

The breeds of this class are provided with prominent breast, and are well developed with excellent fleshing qualities. Fowls of this breed have single comb and horn, coloured beaks, shanks and toes. There are three varieties 'among the sussex as the light sussex, the Red Sussex, and the speckled sussex. The Light Sussex is the most popular among them, and although originally a meat breed, good laying strains have since been' developed which make it a good all-round utility bird. The standard weight of this breed is cock-5 Kg, hen-3.5 Kg, cockered-4 Kg and pullet-S Kg.

II. Orpington.

It is generally a good table bird, but good egg laying strains have also been developed by selective breeding and management. It has single comb. The bird may be Buff, Black, White or Blue. Of these, the buff variety is the most popular. The black is also important as it has led to the development of an increasingly popular breed-the Australorp of this class. The standard weight is c~k-5.5 Kg, hen-4 Kg, cockered-4.5 Kg and pullet-3.5 Kg.

III. Australorp.

This breed was developed in Australia form the blackorpington. It is developed as good egg layer and considerable amount of flesh is obtained from this breed which make it a good dual purpose breed. This breed is gaining more and more popularity in India, and like the Rhode Island Red is well suited for small-sized flocks in the 'backyard' type of poultry keeping, especially in the wet and heavy rain fall regions. The standard weight of the bird is : cock-4.5 Kg, hen-3.5 Kg, cockered-4 Kg and pullet-3 Kg.

IV. Cornish.

It is originally known as Cornish Indian, breed which is said to have been developed in England from the crossing of Indian Aseel and the Malay, and English Game breeds. It is

reputed for its close feathering and compact well-flashed body which has a distinctive shape. The standard weight is cock- 4 Kg, hen-3 Kg, cockered-3.5 Kg and pullet-2.5 Kg.

V. Dorking.

The dorking, like the Sussex, are characterised by long, broad, deep and low-set bodies. Dorking has a rose-comb and the other two varieties have a single comb. All Dorkings have five toes. The standard weight is cock- 5 Kg, hen-3.5 Kg, cockered-4 Kg and pullet-3 Kg.

VI. Red Cap.

The name 'Red Cap' is derived from the large rose-comb which is the characteristic of this breed. It is medium-sized bird possessing a fairly long body and a rather prominent breast. The standard-weight is cock-4Kg, hen;-3 Kg, cockered-3.5 Kg and pullet-2.5 Kg.

Mediterranean Class

There are six breeds classified as Mediterranean because of their origin from the Mediterranean region. These breeds are Leghorn, Minorca, Ancona, Spanish, Andalusian and Buttercup. The fowl of this class are small sized, mature early and good foragers of active temperament but they are non sitters. The maintenance of the fowl is economical as their food requirements are comparatively less. They are good layers.

Leghorn.

Leghorn is small, active and known for the harmony of its different parts. It has a relatively long back, prominent breast and comparatively long shanks. The common varieties of Leghorn are white, brown, black and buff. Some less common varieties are silver-red, black-tailed Red and the Columbian. The white variety has gained popularity all over the world. Next in order of popularity are brown and black. The white, buff and brown varieties are subdivided further on the basis of the character of comb *i.e.* whether it is rose or single comb.

I. White leghorn

It was first introduced into India by foreign missionaries and tea planters about 80 years ago. This variety is not ideal for meat purposes. In India, white leg horn has given good results especially in drier regions, while it does not seem to thrive and produce well on heavy soils and in wet areas. It is most popular as egg producing breed. It matures within 5.5 to 6 months, when pullet starts laying.

II. Brown leghorn

This breed seems to be hardier than the white leg horn and its colours, especially in the chicks, serves as a natural camouflage against predators. This breed is also equally popular because of its excellent productive capacity. It is used for upgrading desi-fowls in areas where birds of white colours are not preferred.

III. Black leghorn

It is not as good layer as the white or brown varieties and is usually mistaken for black Minorca, but can be easily recognised by their head and body conformation of Leghorn. This variety has no special advantage over the other variety of the breed.

Minorca.

It is noticed for its length of body, large comb and long wattles. In fact it is largest of the Mediterranean breeds. There are black, white and buff varieties. The black and white varieties are further sub-divided into the single and rose comb varieties. The most popular is the single comb black Minorca which has an attractive metallic black plumage and an unusually large comb. They are good layers and produce large-size white eggs. The chickens grow fast and are good for table purpose. The standard weight is cock-2 Kg, hen-1.5 Kg, cockered-1.5 Kg and pullet-1 Kg.

Ancona.

The Ancona is of the same general type as the Leghorn. The breed has both the single-comb and rose-comb varieties of which the former is relatively more popular, although the breed as a whole is not so much favoured as the white leghorn. The standard weight of this breed is cock-3 Kg, hen-2 Kg, cockered-2.5 Kg and pullet-1.5 Kg.

5.5 BREEDING IN FOWLS

For successful poultry keeping, systematic breeding of fowls must be practised. The following care should be taken and kept in mind:

- (1) The largest and best farm fowls should be selected.
- (2) The weak, sick and stunt birds should not be taken for breeding.
- (3) Hens should always be best layers.
- (4) Two years old hens should be selected to breed with the cocks of one year age.
- (5) The male fowl should be of different family from the hen with which mated.

(6) The hen must be mated with a cock superior to her.

(7) For successful breeding nutritive food and intelligent management is essential.

For the breeding purposes the cock, selected, should have good size, bone, flesh, broad chest and colour. He should be active, healthy, energetic, young and of one year in age. The hen chosen for breeding should be equally good having almost the same qualities as the cock. If she is active and young she can lay a good number of large eggs. The number of hens allowed to mate with One Cock should be limited and in no case be more than four.

Cross Breeding

For cross breeding purposes a good knowledge of the characteristics of different breeds is essential because all crosses are not good. The first cross of both, the pure hen and pure cock, is the best egg laying but should never be used for further breeding. For cottage industry of the rapid production of eggs and fowls for human consumption, the breeding of cross-breed fowls can be made.

Selection of Best Layer

It is very difficult to select the best layers among the hens. An active intelligent-looking bird, with a bright comb, would always be the better layer than the dull and lazy hen. The thin, sickly, sluggish and poorly feathered hens should always be avoided for breeding. It is said that the greater the capacity the better the layer. The hen in which pelvic bones are fine and wide apart will be good layer. One has to be careful that a very fat hen will not at all be a good layer. Hence the hens should neither be very fat nor too thin.

5.6 EGGS AND HATCHING

The hens normally start egg laying from February and continue till August with some intervals. The hens undergo moulting from July to August so should not be forced for egg laying. Few hens lay from October to January. The best time for egg laying depends upon the climate of a particular region. The rainy season is the best time to raise chickens, because:

(1) There is availability of green food for birds.

(2) Plenty of animal-foods are also found available.

(3) The trees and shrubs are in full foliage to provide protection and shed to the fowls.

(4) The chickens raised in this season grow fast and attain large size which can easily survive in cold season.

(5) The eggs of rainy season are very fertile and hatch out well.

But the chickens should be Well protected from frequent showers arid heavy rains. The chickens hatched from October to the end of January, develop very well throughout India except the hills. The most favourable period in the plains of India is from January to April.

Selection of Eggs

The selection of eggs is very important so following care should be taken:

(1) Eggs of best hens must be set.

(2) The fresh eggs (3-5 days old in hot weather, and 7-10 days old in cold weather) must be set.

(3) The eggs of too small and too large size must be rejected. The eggs should be of ordinary size and of smooth surface which should only be allowed to hatch.

Treatment of Eggs

After placing the eggs under the hen, one should see every day that they ar all right because sometimes eggs get broken in the nest. If any egg is broken the remaining eggs must be removed, washed with water, dried and the ashes and earth of the nest should also be changed. The water used for washing must be at 102°F. The cleaned and dried eggs should be placed under the washed hen in new nest. The infertile and addled eggs must be removed from the nest. The fertility of eggs can be tested by taking a cardboard having hole of an egg shape. The eggs for testing should be held on the hole again strong light. If the egg is found transparent it is infertile but if small body is observed floating in the centre of the egg, it has an embryo. 11 test should be performed after 14 days of egg setting. Another method for testing eggs is to place the egg after 20th day of setting in a large bowl having warm water (102°F). After one minute the eggs, with live chicken will start wriggling in water whereas infertile and addled eggs will float the water surface. On the 20th or 21st day of egg setting the chickens usually come out of the shell. The chickens after emergence do not take food up 30 to 36 hours, so they must be with mother undisturbed for the minimum period of 24 hours.

Precautions for Hatching

At the time of hatching following care should be taken

- (1) Hen should be set at night in a well ventilated and semi dark place.
- (2) Seven or eight eggs should be placed under one hen.
- (3) Before, setting, hens should be examined that they are free from insects. If they are carrying some insects they should be dusted with suitable insect powder.
- (4) Care should be taken of that the hens come out of the nest daily for food. The maize should be given to hen daily. The fresh water and a dry dust bath should also be given daily.
- (5) Hen should be left alone at the time of hatching of the eggs.

Rearing of Chickens

The chickens during their growing stage must be kept under proper management. Different breeds need separate type of nourishment, shelter and exercise. After 36 hours of hatching chickens should be taken out of the old nests with the mother, placed in a clean box or on clean floor under a basket at a dry and warm place. The mother should be given good nutritive food and should be placed with her chickens in the box. After every interval of 2 hours, the food must be given to the chickens in very small quantities. The best food for chickens up to the age of 3 days is stale bread-cumbs moistened with milk and oat meal and broken wheat. Upto the age of 45 days chickens must be fed six times daily. After 45 days to six month's age they must be fed 4 times daily. First feed of the day should be given just after sunrise and last at sunset. Feeding board should always be clean. A very small quantity of 'Poultry powder' given in the soft food to chickens is found to be very much beneficial. A little finely-chopped onions and garlic should be given twice a week. After the age of 45 days, half-cooked meat and raw onion with wheat-bran should be given at an interval of one "day. The earth-worms and white ants are very nutritive for chickens and they feed on them voraciously. After 3 months of age, oil-cake should be given to the chickens once a day. The perfectly clean water should always be kept before the chickens. Very small quantity of potassium permanganate should also be added to the drinking water to protect the chickens from sickness and other troubles. The overfeeding of chickens causes greatest danger to their liver and heart.

The standard ratio of chicken food of 100 Kg is given here as under:

Finely cracked wheat	40 Kg
Finely cracked maize	40 Kg
Cracked rice	10 Kg

Bajra	5 Kg
Cracked charcoal	2.5 Kg
Cracked granulated bone	2.5 Kg

When chickens attain the age of six months, they should be fed three times a day on grain, green food and moist mash at morning, noon and at evening respectively.

5.7 DISEASES OF POULTRY

The poultry keeper should always be careful against the diseases. The most common disease amongst fowls is **RANIKHET DISEASE** which is caused by a filter-passing virus. The Disease affects the fowls of all ages. In this disease bird opens the beak, becomes thirsty, suffers from fever and yellowish white diarrhoea occurs. The crop contains undigested food and the beak is filled with mucus. It is followed by nervous symptoms like twisting of the head, circular walking and wings get paralysed. The birds become very weak and die within 2 to 3 days. Mortality is very high, about 98 to 100 per cent. If a bird recovers it has immunity for life. This disease is transmitted from one fowl to another due to contact with the mucus discharged from the beak: The Indian Veterinary Research Institute Mukteswar (U.P.) has prepared a vaccine which is a boon for poultry industry. The dead birds should be properly disposed of by burying or burning. The chickens should be vaccinated as they attain the age of 40 days. The other common diseases are loss of feather, feather-eating and egg-eating which can be cured by giving large run and some of the poultry powder or tonic mixture. Some diseases are serious but not infectious *viz*; Apoplexy, caused by over feeding; Bumble food due to very large size; Cramps due to exposure in wet or cold: Crop bound, due to over feeding, Diarrhoea, due to over-feeding and dirty water, Dysentery, Liver disease etc. Some diseases are contagious like Chicken-pox, Cholera, Cold etc. The birds should be destroyed and burnt or buried. The disease caused by a tick is known as Spirochaetosis (tick fever). The parasites feed on the blood of fowls in night and leave them during day time. For the prevention of this parasite poultry houses should be made up to 'All metal'. It is advisable for poultry keepers that 'prevention is better than cure' so they must be careful that the fowls should not be attacked by their enemies.

5.8 POULTRY PRODUCTS

The main products of poultry farming are eggs and meat in addition to some by-products like manure, feather etc. In India, the primary aim of poultry farming is to obtain egg. The old, surplus and weak stocks are used for the table. The eggs and poultry meat are among the richest sources of protein and vitamins.

Egg

Eggs contribute to the palatability of a variety of dishes and constitute a rich source of easily digestible animal protein. Eggs are regarded as one of the good sources of vitamin A, riboflavin, phosphorus and iron. As per weight for weight data, an egg contains same quantity of animal protein as poultry meat and pork, about two-thirds that of whole milk cheese, and three-quarters that of beef. Eggs are coagulated on cooking. They provide appetizing foods when fried, boiled and poached. They have a leavening (fermenting) action in some foods such as angel food cake and sponge cake, a thickening action in custard, a combining action in noodles and doughnuts. The eggs are used as binding and coating agent during the preparation of soft breads. The formation of large crystals in ice-cream and candy can be reduced or checked by adding the eggs. The egg albumen acts as a clarifying medium for coffee or soups. It is very much useful in many non-food industries due to the adhesive and coagulating nature of egg white. The number of eggs used for other commercial purposes ego glazing, book binding, medicinal or pharmaceutical preparations, tanning etc. is comparatively very small.

As regard .the structure of egg, it is one of the most wonderful things in nature because of its ability to develop and produce independent life under favourable conditions. The general shape of egg is irregularly ovoid in that one end is broader and some what flatter than the other. This difference in the shape between the two ends is of considerable significance in the development and hatching of embryo. The egg consists of shell and shell membranes 12%, albumen and chalazae 56% and yolk 32%.

Shell:

The shell of an egg composed, mainly, of inorganic salts (chiefly calcium carbonate) forms the hard, rigid and porous protective covering for the soft contents within. The pores allow interchange of moisture and gases like oxygen and carbon dioxide between the egg contents and the outside atmosphere. The number of pores per unit area of the broad end is must larger than that found anywhere else on the surface of the egg. The outer surface of the shell is

covered by a thin cuticular structure. Of the two principal layer of shell, the outer is thin relatively dense and compact, and protects against the entry of bacteria and other unwanted micro-organisms. The inner layer of the shell is granular and besides assisting in maintaining the strength and rigidity of the shell, serves as a source of calcium for the growing embryo. Inside the shell, there are two rough and fibrous membranes, one attached to the shell and the other to the thick white. As the shell contents shrink with cooling and evaporation of moisture, the membranes separate to form the air-cell, usually found at the broader end of egg. The outer membrane can only be separated from the shell with greatest difficulty.

Albumen

(Egg white). The albumen of the egg consists of four different layers. The outer layer of the thin white is just inside the inner shell membrane and forms about 20% of the total white. This layer is directly in the contact of shell membrane except at both the ends of the egg where the thick white comes in contact with the shell membranes. Inside the outer thin white, the layer of the thick white is found which constitutes about 50% of the total white of an egg. Enclosed within thick white is the inner layer of thin white. The inner most very thin layer of thick white surrounds the vitelline membrane that encloses the yolk. The main difference between the thick and the thin is due to the presence of the 'mucin' in the thick white. The chalazae are the coiled cords of thick white, twisted in opposite direction, arising from the thick white layer at each end and terminating in the chalaziferous layer (inner thick white). The chalazae keep the egg yolk nearly in the centre of the egg and give protection to the egg against rough handling. It also helps the yolk to turn easily within the white. The chalazae significantly are of more value as they ensure uniform temperature for the developing embryo during incubation. The white acts as a shock-absorber, protecting the embryo and yolk from damage, and as a source of food for the growing embryo.

Yolk

Beside the blastodisc, the yolk (yellow portion) is the only part of the egg that has its origin in the ovary. The other parts of egg like shell membranes; albumen and shell are added one after another during the passage of the egg through the oviduct. In a fresh egg the yolk rests slightly above the centre because it is lighter than the albumen of egg. The shape of a fresh egg is usually spherical but if egg is kept for some time, the yolk increases in size by taking water from the white and shows a relatively flattened shape than of the fresh egg. The blastodisc or female germ cell is essentially found in the egg but further development of the

egg starts after fertilization by the sperm. Therefore, for incubation only fertile eggs should be taken because the infertile eggs are incapable of development so, they should be disposed off soon.

Composition of egg

The actual composition of egg is based upon the breed of the bird, their habitat and the ecological conditions of the region where poultry farm is located. Whole liquid egg (excluding shell) consists of 36% yolk and 64% white. Protein is the major constituent of white and rest of the white is formed of small amount of sugars, minerals and fat. The two third of solid yolk is fat and one third is protein. The nature of yolk protein is different to that of white. The other constituents of yolk are lactic acid, creatine, creatinine choline and alcohol.

(a) Carbohydrate

The sugar (glucose) constitutes the major carbohydrate part in the egg. The glucose is more in egg white in comparison to the yolk. An average of glucose content in the hen's egg is as healthy egg-0.45%, egg white-0.47% and egg yolk-0.14%. The egg contains very small amount of carbohydrate which yields a reducing sugar on hydrolysis. It is notable that sugar in free form causes heavy deterioration, if present in dry egg products. So, free sugar is eliminated from eggs before drying either by fermentation or by enzymatic oxidation to gluconic acid.

(b) Proteins. Protein constitutes 12% of an egg, of which 64% is from egg white and the rest by yolk. Ovalbumin constitutes about 70% of the total protein in egg white and identified into AI' A2 and A3 proteins. During the storage of eggs this protein is converted into a more stable form 'S-ovalbumin' which is highly resistant to denaturation. Another protein in egg white is conalbumin which is about 17% and reported to be found in two forms like ovomucoid and lysozyme. The egg yolk proteins include vitellenin, livetins, phosvitin, phosphoproteins, lipoproteins, lipovitellin and lipovitellenin. The egg proteins contain all of the essential amino acids required for the development and growth. The egg proteins have been found to be of higher biological value in comparison to the proteins of meat, soya bean, milk, wheat, ground nut etc. The protein of egg white is comparatively highly nutritive than that of egg yolk. The egg proteins possess the functional properties of coagulation, foaming and emulsification which are also significant for the consumers of eggs.

Non-protein nitrogenous substances. The non-protein nitrogenous substances like lecithin, free cholin, ovine, and other bases are also identified in the eggs.

(a) Lipids. The ether-soluble lipids amount to 30-35% of the fresh egg yolk (60-70% on dry basis), and the phosphatids 4 to 12%. Component fatty acids of the glyceride and- the phosphatid fractions of the egg yolk are palmatic, myristic, stearic, oleic, nexadecenoic, linoleic and unsaturated C₂₂ acid. The yolk of hen contains 1.8% of cholesterol.

(b) Vitamins. Eggs are very good source of riboflavin, vitamin A and vitamin D. The different vitamins present in egg are vitamin-A, vitamin-B12 vitamin-D, vitamin-E, vitamin-K, riboflavin, folic acid, niacin, thiamine, pentothenic acid, biotin, choline chloride, pyridoxine and inositol. The losses in vitamin contents during storage of egg are very low.

(c) Enzyme. Some of the enzymes like amylase, diastase, peptidase, phosphatidase, oxidase, various proteolytic enzymes, mono and tributyrases, catalase, tryptic proteinase, lipase, erepsin and salicylase are reported to be present in the egg.

(d) Minerals. Eggs are rich in mineral contents. The minerals like-calcium, iron, phosphorus, sodium, potassium magnesium, sulphur, zinc, chloride, manganese, iodine, copper,fluorine, selenium are reported to be present in the egg. The trace elements present in the egg include lead, chromium, aluminium, molybdenum, strontium, vanadium, titanium and barium.

(e) Pigments. The carotenoids of egg yolk are lutein and zeaxanthin. Ovoflavin, a nitrogenous pigment is also found to be present in the egg. The brown pigment of egg shell is Oorodein, which is identical with hematoporphyrin. The blue-green colour of egg shells, named oocyan, is considered to consist, in part, of the bile pigment biliverdin.

Clearing of egg:-

After laying eggs may become dirty due to so many factors. The dirty eggs should never be washed with ordinary type of cold water. The shell of egg should not be rubbed with the wet cloth or sand paper. For clearing the dirty eggs, sanitizer and detergent (1 % sodium hydroxide) solutions are used. Further it should be washed for 5 minutes in warm water (40 to 43°C) containing a detergent. The egg washing equipment has been developed by the central Food Technological Research Institute, Mysore. With this equipment 1000 to 1500 eggs are properly washed within one hour. This can be used advantageously for clearing eggs on a commercial scale.

Preservation and processing of eggs

The production of clean and wholesome eggs has received considerable attention in the developed and developing countries of the world. Eggs are used for household purposes, for confectionery and for other industrial purposes. About 95% of the eggs are used for table and cooking purposes and remaining 5% are used in confectionery. The urban demand of egg is of prime importance from marketing point of view. In India 20% of the eggs produced do not reach the consumers in a good condition and deteriorate during transport from the place of production to the place of consumption. According to the survey made by the Directorate of Marketing, Ministry of Food and Agriculture, Government of India, the deterioration in the quality of eggs is due to the various factors *viz.*, hot weather condition, storage in warm dry places, dirty eggs, fertile eggs, ungraded eggs and defective packing and handling. It is recorded that 5% of entire spoilage of egg is due to the bacterial contamination. The uncared eggs deteriorate quickly. So, eggs should be collected within a few hours after being laid. The preservation of the quality of egg is of great importance in marketing. The problem is however, beset with great practical difficulties, especially under conditions of village production. For the proper care freshly laid eggs are taken to the egg room, maintained at 16°C and 75% RH, and cooled as soon as possible. Even in cool weather, eggs deteriorate when left in the nest in which hens are laying. Eggs should be collected in suitable wire baskets atleast two or three times daily. The following measures are found to be useful in preserving the eggs.

Production of infertile eggs

The fertile eggs deteriorate rapidly than the infertile eggs at suitable higher ranges of temperature so, the production of infertile eggs instead of fertile ones helps in preserving egg quality considerably.

Infertile eggs can be obtained by separating the cocks from the hens except during the breeding seasons. It is common impression that the presence of a male bird is necessary for the hens to lay eggs. Hens are capable of laying without the presence of cock bird and the eggs thus obtained are infertile. But this is, however, not always possible under the existing conditions of poultry rearing in rural areas, therefore, defertilization of eggs has to be recommended. Defertilization. For the defertilization, eggs are kept in hot water maintained at a temperature range of 135F to 145F for about 15 minutes to destroy the germ. The defertilized egg is equally good as infertile egg and can be kept without deterioration for longer period. In villages, an ordinary long, wide mouthed tin vessel is used for maintaining temperature between 135F to 145F. Eggs to be defertilized are put in an open basket of wire

and dipped into the hot water for 15 minutes after which they are removed and stored in some cool places. In well organised poultry centres, somewhat more elaborated defertilization plants are installed at little cost which consists of water tanks with mechanical stirrers electrical heating arrangements, some wire baskets and egg cooler.

Egg cooling.

It is well known that temperature above 68°F is favourable for the development of embryo and consequently makes for rapid deterioration of egg quality. A temperature below 68°F is suitable for maintaining the quality and freshness of the egg. In winter season, cooling devices is not needed when temperature is normally below 68°F but when temperature is higher than 68°F, a cooling device is necessary. The ideal of course, is refrigerated coolers. Some of the cooling systems which can be adopted by poultry farmers are given below.

(a) Cool room. Egg room can be cooled by providing all the outlets with khus tattis kept constantly moist by sprinkling water on the floor. If possible, a ceiling fan will be very much helpful for cooling the room.

(b) Underground cellar. If a cool room is not possible an underground pit should be made which can provide desirable low temperature for the proper cooling of eggs.

(c) Earthen pot. A large earthen pot can be maintained at lower ranges of temperature by keeping it partially buried in a sand heap on which water is sprinkled frequently. In the bottom of pot a layer of dry straw or hay should be kept to avoid the percolating dampness. The pot should be kept in well ventilated place and the mouth of the pot should be covered with thin muslin so that air and moisture can pass freely inside the pot.

(d) Cold storage. The egg quality is fairly well maintained for about nine months in cold storage at 0°C and 85% RH. In India the cold storage of egg is now under practice in well organised poultry farms but in rural areas where refrigeration facility is not common, the cold storage of eggs has been taken upon a large scale.

Freezing eggs

It is One of the best means of conserving the quality of eggs. In this method deterioration is arrested, and the frozen eggs can be held in cold storage for an extended period until needed. In this method, shell eggs are placed in cold storage to preserve the quality. After thorough chilling, eggs are taken to candling room. After the eggs are candled, they are transferred to the breaking tables, where the shell is broken against a blunt knife located above a small tray

which is supplied with cups to hold the contents of the egg. Separated yolk, and white, or mixed whites and yolks, can be preserved through freezing which checks the growth of bacteria. Frozen whole eggs are used for preparing cakes, pastries, ice-cream etc.

Drying eggs

The drying of eggs is more convenient way of preserving the eggs than even freezing. The drying process reduces eggs to about one-fourth of their original weight, so that about 70 normal-sized eggs make 1 kg of the dried product. The dry egg products like dried whole egg, dried yolk and dried whites, are prepared in farms. In this method the egg pulp is forced under pressure into a drying chamber and sprayed through a nozzle, The incoming air is held at higher ranges of temperature while the exhaust air has a temperature of lower ranges. The spray dried product is usually a fine powder while the pan dried product is made up of flakes or scales which can be ground into powder.

Lime sealing of egg

The lime sealing of eggs prevent the evaporation of moisture and escape of carbon dioxide through shell pores. For lime sealing, shell eggs are dipped for about 18 hours in lime water, containing powdered salt.

Oil coating of egg

The oil coating of shell egg for conserving the quality of egg is an economical and convenient method for common poultry farmers. The oils used for this purpose are carnation oil, a white mineral oil refined from paraffin and coconut oil. The Central Food Technological Research Institute, Mysore has developed a perfect method in which eggs are coated with oil- based on a petroleum product to which some fungistatic and bacteriostatic agents are added. The eggs, kept in wire baskets are dipped for 5 to 10 seconds in a vessel containing the coating oil. Further, baskets having eggs are taken out from the vessel and hung on a hanger for about one hour. During this period fan can be used for proper drying of oil coated eggs. The dried eggs are ready for storage. The coating oil in the vessel can be used for many times with proper filtration and sterilization so that oil may not get dirty. The oil coated eggs can be kept for about 30 days at room temperature (25-27°C) and 80 days at 13°C. Oil coating should be done as soon as possible after the eggs are laid. The oil should be colourless, tasteless and odourless.

Water-glass method

It is a good method for preserving the quality of eggs. For this purpose, commercial water-glass (sodium silicate) is mixed with cooled boiled water in a definite ratio and is kept in an earthen pot and both are mixed thoroughly with an wooden piece. Eggs are dipped in the above solution and covered pots are kept in a cool place.

Products of egg

A number of useful products like albumen flakes, frozen egg yolk and egg powder are prepared from eggs.

1. Albumen flakes: For the preparation of albumen flakes, the thick albumen of egg is broken by the microbial fermentation and glucose is removed. Now this content is acidified and dried in the form of albumen flakes. The albumen flakes are used for the preparation of sensitive mixtures for coating zinc or aluminium foils for offset printing. The flakes are also used for the tanning of costly leather.

2. Frozen yolk: The yolk obtained as by product during the processing for albumen flakes are used as such or frozen for use in various purposes. The major products of frozen yolk are plain yolk, sugared yolk, salted yolk and yolk emulsions. Sugared yolk and salted yolk is mixed with 10 per cent sugar and salt respectively which acts as anticoagulant and minimise the chemical changes in yolk during freezing but they affect physical properties of yolk. Another method for the preservation of frozen yolk is by the addition of 6 per cent sodium chloride and 1 per cent of sodium benzoate to it. The frozen yolk after treatment with 0.04 per cent pepsin can be kept undamaged for about four months.

3. Egg powder: For the preparation of egg powder, eggs are cleaned in running water, dipped into 2% solution of bleaching powder. The cleaned eggs are broken and liquid thus obtained is churned and filtered to separate pieces of shell and chalazae. For the removal of sugar, 0.5% yeast is added and kept at 36°C for 1.5 hours. Now fermented liquid is pasteurized at 60-61°C for about 30 minutes, cooled and 1 N HCl is added to bring the pH to 5.5. This solution is spray dried at an inlet temperature of 160°C and an outlet temperature of 60°C, keeping the automizer at 20,000 r.p.m. Thus the egg powder is obtained which is further kept in vacuum self-drier at 60°C for about 3 hours. In this powder 1.2% sodium carbonate is added and is canned in sealed containers. The egg powder thus obtained consists of moisture 13-15%, protein 45%, lecithin and fat 38-40%. The dried egg powder can be kept for long period even at higher ranges of temperature. It is very easy to transport the egg powder and

the proteins are with the same amino acids as in shell egg. For the preparation of custards, pies etc. the egg powder is commonly used.

Poultry Meat

The use of poultry birds for table is gaining more and more importance in our country which is managed either as a separate enterprise or in conjunction with commercial egg production. The birds for table should be well-fleshed on thighs and breast, fast growing and should have ability for high ratio of gain in live weight to the feed consumed. The weight of mature chicken may vary from 1 Kg to 5 Kg' according to the species and feed of birds. The leg represents more of total weight in male chicken in comparison to the females. For the purpose of human consumption, poultry meat should be soft, sound, clean and healthy. It contains less fat than other meats. The tenderness and flavour of meat is influenced by the age and sex of the bird. Chicken upto 85 days of age have a very tender meat and between 85 to 115 days of age have tender meat which can be cooked by roasting. The meat of mature hens is not soft for table purpose.

Composition of poultry meat

The use of table birds is gaining more and more success as meat is a good source of protein, vitamins B, phosphorus and iron. The losses of these constituents are least during the course of cooking particularly with respect to vitamins B.

Nitrogenous substances The protein of poultry muscle consists of extracellular protein which includes actinomyosin, globulin X, myogen and myoglobin. In addition, other nitrogenous substances like creatine, carnosine, anserine, adenosine triphosphate, urea, ammonia, uric acid and amino acids are found *to be present in crude poultry* muscle. The *bones* are made up of *calcium phosphate* and collagen. The collagen of skin is changed to gelatin at the time of the poultry cooking which gives a desirable flavour to *the* soup. The poultry proteins are provided with highly digestible constituents and essential amino acids.

Fat The distribution of fat constituent varies in accordance with the age, sex, nutrition of the bird and tissue. The abdominal tissue contains about 80% fat, while the breast tissue contains very low (0.3%) fat percentage. The fat may be either neutral fat or phospholipids which contain tetraenoic, pentaenoic and hexaenoic acids. The acidity of the fat is taken as an index of freshness. The increased acidity of fat indicates the deterioration in the poultry meat.

Enzyme Many enzymes like lipase, catalase, oxidase, peroxidase, reductase, amylase, invertase, glycogenase, maltase, proteinase and antitrypsin are found to be present in the poultry fat and muscles.

Minerals A large number of minerals like calcium, potassium, sodium, iron, phosphorus, magnesium, chlorine and sulphur are reported to be present in the poultry muscles. Phosphorus and iron are found in good quantity. The trace elements like copper, iodine and manganese are also present in the poultry muscle.

Vitamins The poultry meat is very good source of riboflavin and nicotinic acid which is directly related with the nutrients given to birds. The other vitamins like vitamin A and vitamin D are present in the liver. The dark muscles of chicken are good source of thiamin and riboflavin.

Processing the Bird for Meat

The killing of bird for table purpose, dressing and evisceration (to disembowel) come under the poultry processing. Some consumers prefer to purchase living birds while some wish to buy dressed bird as per their requirements.

Dressing Before killing, birds should be housed and should be given sufficient food and water. Before 3 hours of slaughter, feed should be taken away from the birds but water should be there for all the time. The carotid arteries are cut for complete bleeding because incomplete bleeding results in a dark, unacceptable product. Feathers are removed by immersing the bled bird in water at particular temperature for 3-5 minutes which is termed as, scalding. Further, feathers are removed by hands or by some simple mechanical measures. The hairs from carcasses are removed by passing them through a hot flame after drying.

Evisceration Commonly birds for table are purchased in eviscerated or ready-to-cook form so proper care must be paid to save from bacterial infection, rancidification of fat and much moisture losses.

Chilling and freezing Just after dressing, the carcass should be first kept below 4-5°C and further at 0°C. The process of chilling is performed by slush ice for sudden fall in the body temperature of carcass so that excessive desiccation of the carcass may be checked. Thus, the carcass can be stored in good condition for 20 to 30 days. One should take care that faeces of the bird itself may not come in contact with the carcass to avoid the contamination during this process. During the course of chilling, the free amino acids and basic nitrogen content of meat slightly increases but at the expense of proteins. If the poultry meat is kept below -9°C

temperature, the losses due to microbiological activity ceases as a result the souring and sliming of meat do not affect the quality of meat. Now-a-days, with the advancement of poultry industry in India, large poultry processing system have been established at various centres which have very good capacity for the poultry processing.

Canning For facilitating the distribution and storage of surplus poultry meat canning is very useful method for maintaining the quality of meat. In canning, the meat is sterilized and protected by a pack container particularly where refrigeration facility is not available.

Meat Products

Canned chicken The old hens after the age of 20 months become uneconomical for egg laying so they are canned for regular supply of poultry meat. The central Food Technological Research Institute, Mysore has developed methods for canning solid-packed processed chicken in the form of whole chicken, whole boneless chicken, cut-up chicken without bone, cut-up chicken with bones and selected parts such as breast, thigh etc. In the process of canning chicken broth and chicken jelly are obtained which are used in the preparation of tonics.

Sausages The small pieces of meat obtained from old hens, roosters and culled birds are mixed with vegetables and after seasoning with spices they are converted to sausages. The product consists of moisture 62-65%, protein 15-17%, fat 15-17% and carbohydrates 3-4%.

Chicken essence The pieces of meat of healthy young chicken are partially hydrolysed with boiled water and extract is concentrated under vacuum. Further, this concentrated extract is sterilized and fat is removed and diluted to required standard. Now suitable preservatives are added and the contents are sealed packed.

Baby food Some of the baby foods, as a good source of protein, iron and nicotinic acid, are prepared by the meat and broth. The skin and bones are used for the preparation of skin paste or dehydrated product. The baby foods are devoid of any fibre.

Feathers The feathers of poultry birds are of good commercial purpose. They constitute 4-9% of live weight of bird. They are washed, dried and packed for commercial uses. Feathers are utilized for making pillows and quilts. Due to their light weight, softness and high insulating power the down feathers are of great demand in foreign countries. Since long feathers are under use for making shuttle cocks.

Poultry manure The poultry manure, obtained from the dropping of poultry birds, and constitutes nitrogen 2%, phosphoric acid 1.25% and potash 0.75% so it is highly valuable for the standing crops in the field. Forty birds can give nearly a ton of deep litter per year which is sufficient for fertilizer needs of a hectare of maize or paddy.

By-product feed. A number of poultry by-products like blood-meal, feather-meal, poultry by-product meal and hatchery by-product meal are used as good sources of nutrients for meat producing animals and poultry. These by-products supply protein, essential amino acids, fat, vitamins and good amount of minerals. The feathers obtained from poultry slaughter house are treated under high pressure and feather-meal or hydrolysed feather is formed which contains, 80 per cent protein of which 70 percent is highly digestible. To obtain the poultry by-product meal the dryrendered parts of the carcasses of slaughtered poultry like head, feet, undeveloped eggs, gizzard and intestine are grounded. A mixture of egg shell, infertile and unhatched eggs and culled chicken are cooked, dried and grounded to obtain poultry hatchery by-product meal which contains calcium 18.1 %, 413 *mgl* 100 g of phosphorus and essential amino acids.

5.9 SUMMARY

Poultry farming is the practice of raising domestic birds like chickens, turkeys, ducks and geese, as a subcategory of animal husbandry for meat or eggs for food agriculture. A hen begins to lay eggs when it is six months old and the egg laying bird is called 'broody hen. The eggs collected are called laying hens while the chickens bred for meat are called broilers. Most poultry are raised in intensive farming techniques. Seventy four percent of poultry meat in the world and 68 percent of eggs are produced in this way. Poultry farming involves breeding and raising chicks for various purposes, in egg producing farms, birds are typically housed in rows of battery cages. High yielding varieties of chicken include Aseel, Ghagas, Basara and Brahma found in different states of India. High yielding foreign breeds or exotic breeds are classified into four classes namely, American, Asiatic, English and Mediterranean based on the geographical area they have evolved in. These classes comprise breeds that are reared for eggs, meat, or both.

A good crop of eggs is obtained by keeping poultry healthy. It is important to ensure nutritious feeding and proper housing. Chicken on a poultry farm are fed with grains, groundnut cake, rice husk, wet mixtures and green food to eat that are rich in carbohydrates, proteins fats and minerals. Poultry is routinely medicated, by antibiotics, in feed or drinking

water, to treat disease or to prevent disease outbreaks arising from over-crowded or unsanitary conditions.

Poultry farming is a booming business, which can provide employment opportunities to small farmers and give them supplementary income along with nutritional support. Poultry contributes to improved human nutrition and food security by being a leading source of high quality protein in form of eggs and meat. It acts as a key supplement to revenue from crops and other livestock enterprises, thus avoiding over dependency on traditional commodities. For smallholder farmers in developing countries poultry represents one of the few opportunities for saving, investment and security against risk. In some of the countries, family poultry accounts for approximately 90 percent of the total poultry production. Poultry is the smallest livestock investment.

5.10 SELF ASSESSMENT QUESTION

Long Answers Type Questions

1. Explain the food & feeding habits of the poultry?
2. What are indigenous breeds, explain with suitable examples?
3. Explain the economic importance of poultry & its products?
4. Write a note on Diseases of poultry?
5. Describe exotic breeds & their economic significance with examples?

Short Answer Type Questions

1. Which exotic breed is best for egg production?
Ans. White Leghorns
2. What is the most important ingredient in a good poultry feeding ration?
Ans. A constant supply of clean, fresh water
3. How long is the incubation period for chicken eggs?
Ans. 21 days
4. What is a female chicken less than 1 year of age called?
Ans. Pullet
5. What is the collective term for the feather covering of a bird?
Ans. Plumage

Fill in the blanks:

1. _____ acts as bird's teeth by grinding the food.
2. _____ type chickens are more prone to malfunction.
3. Indian indigenous breed are _____, _____ & _____.
4. The most common disease amongst fowls is _____.
5. A poussin is a type of _____.

Multiple Choice Questions

1. The hatchery should be situated at least how much distance away from other poultry houses.
a) 100ft b) 500ft c) 1000ft d) none of the above
2. For maximum egg production, the photoperiod is
a) 8 hours b) 14 hours c) 18hours d) 22hours
3. Fresh poultry excreta contains.....% water
a) 50-60% b) 60-70% c) 70-80% d) 80-90%
4. During incubation testing of egg should be done at
a) 10th day b) 15th day c) 18th day d) 21th day
5. A guinea fowl is a
(a) Young pigeon
(b) Castrated chicken
(c) Rock Cornish game hen
(d) Relative of the pheasant

Answer:

Fill in the blanks:

1. Gizzard
2. Meat
3. Aseel, Malay & Ghagus
4. Ranikhet disease
5. chicken

Multiple Choice Questions:

1. c
2. b
3. c
4. c
5. d

5.11 GLOSSARY

Anthelmintic: medication given to treat a bird with internal parasites

As hatched: description of a group of chicks that have not been sorted

Avian: pertaining to birds

Axial feather: the short wing feather located between the primary and secondary flight feathers

Banding: putting a tag or band with identification on it to the wing or leg of a bird

Bantam: a chicken breed that is one third to one half the size of a standard breed.

Beak: the hard protruding mouth part of a bird consisting of an upper and a lower part

Bedding: material scattered on the floor of a poultry house to absorb moisture and manure (also called litter)

Billing out: the act of chickens using their beaks to scoop feed out of a feeder and onto the floor

Broiler: a meat type chicken

Broody: a hen that is sitting on eggs with the intent of hatching them

Chick: young (baby) chicken

Cluck: sound a hen makes after laying an egg

Coccidiosis: a parasitic infection (coccidia) in the intestinal tract of poultry

Comb: the fleshy red outgrowth on the top of a chicken's head

Contract grower: a farmer that grows chickens, under contract, for a broiler company

Coop: the house or cage in which poultry are housed

Crossbred: the offspring of parents from different varieties or breeds

Crumbles: a poultry feed that has been pelleted and then the pellets broken up

Cull: to remove a bird from the flock because of productivity, age, health or personality issues

Depopulate: to destroy an entire flock

Dressed: cleaned in preparation for eating (feathers and guts removed)

Forage: to scratch the ground in search of food

Fowl: domesticated birds raised for food or other similar purpose; also refers to a hen at the end of its productive life

Fryer: a young meat type chicken

Hatchery: a place where eggs are incubated and chicks hatched

Hen: adult female poultry including chicken, turkey, duck, pigeon, pheasant, etc.

Mite: a type of external parasite

Molt (Moult): a part of the hen's reproductive cycle when she stops laying and loses her body feathers

Mounting: when the rooster mates with a hen

Nest egg: artificial egg placed in a nest to encourage hens to lay there

Pecking order: the social rank of individuals within a flock

Perch: the area above the ground where birds will sit, primarily for sleeping at night

Plumage: the total set of feathers covering a bird

Poultry: a term for domestic fowl raised for meat, eggs, feathers, work or entertainment

Roaster: a meat type chicken raised to a size that makes them suitable for roasting

6.1 OBJECTIVES

After reading these units we will know about the Economic Importance of Mammals in Agriculture, Horticulture, Dairy product, Leather product and leather industries and Wool and Fur Industries.

6.2 INTRODUCTION

Mammals have attracted the attention of human beings since time immemorial because *Homo sapiens* have been always gazing for their food, shelter, protection and comfort. The status of mammals may be considered from the point of view of their value in nature and also to their importance in raising the economy of mankind. Mammals have always dominated the regions they inhabit and thus influence the direction of evolution and maintain a balance of complex ecological conditions.

6.3 ECONOMIC IMPORTANCE OF MAMMALS IN AGRICULTURE

Mammals have attracted the attention of human beings since time immemorial because *Homo sapiens* have been always gazing for their food, shelter, protection and comfort. The status of mammals may be considered from the point of view of their value in nature and also to their importance in raising the economy of mankind. Mammals have always dominated the regions they inhabit and thus influence the direction of evolution and maintain a balance of complex ecological conditions. But man has treated only those mammals with respect who may be of direct value to him. The comprehensive account about the importance of mammals may be assessed into two sub-divisions:

- (1) Indirect value of mammals,
- (2) Direct value of mammals.

Indirect Value of Mammals

The phytophagous mammals greatly influence the flora of an area, for example the short-grass prairies were certainly affected by the millions of Bison, Prairie dogs and other herbivores that inhabited them. In nature a large number of lagomorphs, rodents and ungulates damage the trees by feeding on bark but others, help to reseed the vegetation by burying nuts and seeds. Seeds of many plants are spread when they pass out through the digestive tract of mammals or by being attached to their hairs. Pollen eating and nectar feeding bats cause pollination in a number of plants. In grass lands, where there are large number of fungulates, the soil enriching effect of mammal's droppings is also of great value.

The activities of carnivorous mammals like foxes, cats etc. are also of much importance in controlling the number of mice, rats, and other rodents and rabbits. The detailed ecological study of carnivores suggests that even sick and weak from the population should not be removed. So carnivores are the necessity of natural community to control the number of herbivores, and the population of carnivores are, in turn, regulated by the abundance of prey species. Literature regarding this reveals that the relationship of herbivorous and carnivorous mammals has not been well studied purely from ecological point of view.

Direct Value of Mammals

For the comprehensive study of economic importance of mammals two categories can be made *vir*. Usefulness of mammals and harmfulness of mammals.

Usefulness of Mammals

Mammals which promote welfare of human-being are known as useful mammals. For proper study, the useful aspects can be grouped into 4 categories:

- (1) Direct use of mammals,
- (2) Use of mammal products,
- (3) Other commercial products,
- (4) As zoo and laboratory animals,

[I] Direct use of mammals

Some mammals are helpful to human beings with regard to their activities. They are used for agricultural, and transport purpose, as scavengers, in hunting and sports, as pets and predator of pest mammals.

1. Agriculture. Even in the era of advanced science and technology a large number of mammals are employed in agricultural work. Mammals like ox, buffalo, camel etc. are commonly found to be used for the 'tilling of the soil. Due to tilling, the soil becomes highly fertile because of its increased water absorbing capacity; aeration of soil and reaching of organic materials to the lower levels. Buffalo, ox and camels are also used for irrigation of crops specially in the areas where other irrigation facilities are not available. The dung and urine of cow, buffalo, sheep, goat etc. are used in the form of highly nitrogenous natural manure. This manure is also used in gardening for good sized flowers and fruits. Manure is also prepared from the remains of the whaling products and the guano of bats dug from the floor of caves. It is also a rich and valuable fertilizer.

2. Transport A large number of transport facilities have been evolved and are being used in various fields but many mammals are also used for the purposes of transport at different places. Man has expert and trained horses, ox, camel, buffalo and elephants for the transport either in cart or as such. Camel, ass, donkey, horse, and elephant are used as beasts of burden. Camels are widely used in desert for transport purposes. Certain mammals are used for transport in specific regions e.g., Reindeers and Tundra dogs in Tundra Pradesh, Yak in Tibet and Bison in America.

3. Scavengers The importance of mammals as scavenger can not be ignored. Without this valuable aid of the mammals the whole of the world would be an open sewer. Hyaenas, jackals and pigs always function as natural scavengers due to their feeding habit. Sometimes it is found that dogs are also feeding on the excrement of human-beings.

4. Hunting and sports From time immemorial hunting has been of interest to human-beings for recreation and men in all parts of the world engage themselves in this activity. Sport hunting is commonly considered to be of two types *i.e.*, 'big game' and 'small game'. The big game may provide protection from a number of larger carnivore's *viz.* lion, wild boar, tiger etc. and also may be used as food. For this game, hunter usually has to travel far from his home. The fur hides and skins are also obtained in big games which are a good source of money. The small game is generally restricted to the smaller mammals such as rabbits, squirrel etc. and is played locally. In small game the use of weapons is not essential. Some persons are professional hunters. A number of larger mammals are becoming extinct, so their hunting is strictly prohibited now-a-days. Mammals like dogs and horses are quite helpful at the time of hunting.

5. Pets The dependency of human-beings on mammals led to domestication of some mammals for proper care and continuous supply of some useful materials in daily life. Before pre-historic period domesticated mammals had started to act under the direction of man. Dog was probably one of the mammals domesticated even before the written history. During-the course of hunting dog provides its superior and sincere help about the presence of small and dangerous predators. It also follows the foot steps of the prey, harasses them and even may kill finally. At some places the dogs are used for transportation, guarding, herding and protection of live stock, food, skin etc. The sheep and goats have been domesticated since 9,000 years. Cattle, water buffalos and horses have been domesticated since 6,000 4,000 and 4,000 years respectively. Apart from these mammals, human-beings use many other mammals either as domestic or as domesticated lots. Thus, it is concluded that man is greatly dependent upon pet mammals for a number of functions, so pet mammals like dogs, cats, cattle; sheep, goats etc. are generally found in association with civilized man. Bernett (1948) discovered that policedogs assist the police department by tracking down culprits by their distinctive smell.

6. Predator of pests The role of pest predating mammals is of much importance. They reduce the population of some pests which are damaging the economy of the nation. So, there are certain restrictions on the hunting of those mammals who prey on pests. Next aim behind the restriction of hunting of those mammals is to preserve the species in nature. Cat is one of the most important mammalian predators which prey upon rats which is very serious pest of food grains in houses and crops in the field. In a number of government offices cats are used predating on rats and thus help in reducing the number of rats. The Humburg Government has fixed a special budget to provide milk and meat for 10,000 domesticated cats. Humburg is a very big port of the world where food grains are loaded and unloaded in huge quantities. Mongoose is the other mammal predating on rats. Foxes also cause great harm to the population of rats. Bhatia and Singh in 1959 have mentioned that squirrels entering in the cages of locusts prey on the hoppers and adults both.

[IT] Use of mammalian products

The mammalian products are being used in various ways by human-beings in the form of food, shelter, medicine, oil, musk and also as some other commercial products.

1. Food Food is the first necessity of life. The food value of mammals is in the form of meat, milk and their products. With the increasing number of domestic mammals and good transport facilities, man has increased his dependence upon non-vegetarian diet, obtained from mammals. Eskimos use essentially the marine mammals for their food. Kangaroos and wallabies are very important for the food of Australian aborigines. Although hunting is known to be a sport but a number of mammals after hunting are used as food e.g., rabbit, squirrel, deer, whales, seals etc. A number of ungulates as cattle, goats, sheep etc. provide very nutritive food to human-beings. The pork and beef are taken as major food materials throughout the world. Many tribes of the Andaman and Nicobar Islands (Jawa, Hoichus, and Oongees) prefer to feed on the flesh of pigs. Thus, mammals are used as highly proteinous non-vegetarian diet for human-being throughout the world.

The use of mammalian milk has proved to be a boon for mankind since time immemorial. Milk has provided life for the man. Mammals like cow, buffalo and goat provide milk for human consumption to take as such or in the form of butter, curd and ghee or for the preparation of other edible materials. Dairying has been a good business for the earning of money in cities but in villages the milk, curd and ghee are small sources of income especially to the poor people.

Denmark, Holland and Belgium have developed advanced techniques in dairying industry and thus they can earn good money. In India adequate efforts have not been made to establish improved dairy. Once upon a time India was greatest source of milk in the world and thereby cow was regarded as 'mother' by the 'Hindus' but now-a-days due to lack of uncultivated land and other facilities mammalian milk is being less consumed by man day-by-day. The other reason is its high cost which is beyond the reach of common man. Although Government of India has planned some schemes to improve the dairying industry but the results are not very satisfactory due to lack of proper management and its being restricted only up to cities.

2. Shelter The mammalian skins, hairs and furs are used for the protection and covering of the human body. Now-a-days mammals are probably being used more for shelter as compared to that of food. Wild boars, peccaries, kangaroos, seals, sea lions and capybaras are hunted for their hides. So called fashionable and rich people use furs of soft texture for their coats, particularly their ladies' must have fur at least around their neck. Thus, fur trade is subjected not to the actual needs of human-beings but to social whims. In India alone out of

1/5th of the world's out-put of hide and skin 1/3rd is obtained from goats. But in the world market of hide, India has not been able to provide good quality material. Soni (1969) calculated from some data that India produces hide and skin worth 50 crores rupees annually.

The most common fur yielding domesticated mammals are beaver, mink, otter, shrew, fox, sheep, goats, cats and rabbits. The hair and wool of sheep and goats are spun into thread and woven into fabrics.

3. Medicine The mammals are also of great medicinal value. The cow and goat milk is given to diseased persons because of its easily digestible property. The whale liver provides a good quantity of vitamin A which is highly recommended for eye diseases and proper maintenance. Some mammalian organs like kidney, pancreas, liver, and some hormones, secreted by endocrine glands *viz.*, adrenal, thyroid, pituitaries and thalamus are used directly or in the form of their extracts to cure the disease of human-beings.

4. Oil Before the knowledge of petroleum, the oil obtained from mammals was in much greater demand. Whales are still hunted for their oil which is used primarily in the manufacture of soap and margarine in paints and for softening the leather. The renowned 'Sperm oil' a waxy inedible fat was used for candle manufacture, but today it is being used in cosmetics and ointment, as a lubricant for fine machines and in the manufacture of detergents and shoe polishes.

5. Dung Cow dung is a good source of natural nitrogenous fertilizer. Some people in villages use dried dung as fuel for cooking the food materials. In recent years cow dung is being used in small scale industry of Gobar Gas Plant. The gas obtained from this plant is now widely used in villages for light and cooking purposes.

6. Musk Musk is known since pre-historic period and has been mentioned in several old literatures. It is produced by Asian and African civet, American skunks and musk deer. Musk is widely used as a base in perfume industry. Ambergris, a waxy substance found in the intestine of some sperm whales and formed by certain abnormalities in the function of the intestine is also used in perfume industry as fixative.

7. Ivory It is also well known since very old time and is obtained from elephants and walrus. It is very much valuable and is used for piano keys, billiard balls, in knives etc. The

hippopotamus teeth, narwhal tusks and the teeth of sperm whales are also sold for ivory purposes.

[III] Other commercial products

1. Hides and skins The hides and skins are tanned and used for the preparation of number of articles like purses, cases, belts, shoes, sandals, slippers, suit cases etc.

2. Carcass From the carcass of mammal's fat is obtained and is used widely in the preparation of soaps and lubricants in leather and textile industry. From the carcass of a healthy mammal 5 to 50 pounds of fat can be obtained according to the size and health of the animal. Tennis and badminton rackets are prepared from the iritestine of some mammals. Now-a-days, there are 250 flaying carcass and 250 marketing depots in the small scale industry sector.

3. Horns and hoofs The horns and hoofs are consumed in the preparation of fancy toys, combs, frames, handles of knives, buttons etc.

4. Hairs The hairs obtained from pigs, camels and horses are used for the preparation of brushes of hard nature *viz.*, for polishing the shoes, painting, coat brush etc.

5. Skeleton Bones of the dead mammals are of great economic value and are used for the preparation of weapons for defence and offence both. Bone-charcoals are used in sugar industry for clearing mollases. The bones of elephant and camel are of high cost in the markets. Gum and gelatins are obtained from the skeleton of whales and are used in the manufacture of candles and photographic films etc. The bones of mammals are widely used for the manufacture of phosphate fertilizers like super-phosphate which now-a-days is commonly used by farmers in their cultivated land for good growth and production of crops.

[IV] As zoo and laboratory animals

A large number of mammals like lions, tigers, deer, bears, monkeys, rabbits, foxes, elephants, camels, blue bulls, hyaenas, wolves, etc. are well maintained in a number of national and international zoological gardens and parks. A lot of visitors see them from a close range for their entertainment whiles some from academic point of view also. So, it is a good source of

income. Some mammals like rats, jackals, rabbits, squirrels, monkeys are used widely in research laboratories for investigations in various fields. Thus, apart from economic benefits mammals are quite useful from academic points also.

Dairy Industry

The dairy industry, covering the production, processing and distribution of milk and milk products is unique in its importance as it is concerned with valuable food stuffs universally consumed by man. Milk is the fresh lacteal secretion of milch animals naturally intended for the nourishment of the offspring, but exploited as an article of food by human-beings. The young ones of other mammals survive only upon their own mother's milk but man uses milk of other mammals as additional source of nutrients for his offspring as well as for himself. Man also uses mammalian milk for a variety of preparations like curd, butter, chees, sweet etc. For the proper and regular supply of milk, man has domesticated a number of mammals. The only mammals which have received attention worth the name are cows, goats and buffalos. The other animals like sheep, cammels, asses and mares are milked in certain confined localities but as producers of milk they are of little importance.

The dairy cattle thrive best in areas where pasturage and other green forage are grown in abundance. Extremely cold climates are not suitable because of the lack of green forage and much expense for protecting the animals from the weather. The modern dairy industry is somewhat recent in origin. In earlier phase cows were kept to furnish milk for the farm family. The marketing of milk began when customers called at the farm or farmers to distribute their milk directly to users. Within the past 100 years advances along five different lines have caused milk and milk products to become important articles of commerce:

1. The processing of milk by factory system was started in the middle of 19th century, resulting in greater uniformity of product.
2. A number of technological advances like concentrating milk and sealing it in container in sterile conditions, distribution of milk in bottles and other advanced processing of milk began.
3. The first milk sold in towns and cities came from nearby farms. The knowledge of refrigeration of milk not only aided in keeping milk fresh for a longer period but also made possible the shipping of dairy products to all parts of the world.

4. In earlier days the method of transporting milk to large cities was to ship it on railways. The motor vehicles and paved roads made possible the supplying of fresh milk to markets hundreds of kilometres distant from farms where the milk is produced.
5. The adoption of pasteurization and the enforcement of laws requiring proper food value in dairy products greatly benefited the entire dairy industry.

Breeds of Dairy Animals

Cow

The number of well recognised cow breeds in India is about fifty. In addition, a large number of other types which do not conform to any definite breed characteristics exist, and are treated as non descriptis. The nondescriptis are very poor producer of milk. The principal breeds of cows are Haryana, Kankrej, Ongole, Rath, Deoni, Gir and Kangayam. Deoni is found in the locality of North-western and western parts of Hyderabad and are good milkers in the region. Gaolaois common in Ward ha and Chindwara districts. Gir is good milker and found in Kathiawar, Rajputana and Baroda regions. Haryana is very good milker found in the vicinity of Rohtak, Hissar, Karnal, Delhi and Uttar Pradesh. Kankrej is common in South east of Rann of Kutch and Ahmedabad region and is fair milker. Ongole is also a good milker and found in Guntur districts. Rath is fairly good milker which is found from Rajasthan to North-western part. Shahiwal and Sindhi are very good milker found in Punjab, Haryana and Uttar Pradesh.

Buffalo

The buffalo is generally regarded as a very good dairy animal in India. The breeds of buffalo are lesser than cow. Murrah is very good milker which is distributed throughout Punjab, Haryana and Uttar Pradesh is a good milker and found in forest regions of Kathiawar. The breeds of Niliand Ravi are common near Ferozepur district of Punjab and are very good milk yielding varieties. The Surti are economical milkers and common in Gujarat.

Goat

The goats are used all over India for supplementing deficiencies in milk production. About 20 per cent of the goat population is used for milk production. Though there are many breeds of goats, some are used commonly in different regions of India. The various breeds of goat which are good milkers, are Jamunapari in Ganges-Jamuna riverine tracts. Beetal in Punjab, Bar-bari in Uttar Pradesh but not giving good results in Tarai belt; Outchi in Kathiawar and Kutch, Osmanabad in Hyderabad region, North Gujarat in Kathiawar, Kutch and North

Gujarat, Marwari in Jodhpur, Surti near Surat, Sirohi in Sirohi and Palampur and Malabari in North Malabar region.

Breeding

Near about the middle of the 18th century, dairy farmers began the improvement of cattle and other farm livestock. The chief practices followed were the mating of related animals and close culling. The rearing and maintenance of proved and standard breed for distribution upto village level is undertaken in Government farms. The bulls are used for selective breeding in areas of well-defined breeds. Attempts are being made to upgrade non-descripts in several areas by repeated forward crossing. These attempts have given encouraging results but the number of bulls available for breeding purposes is inadequate. The progeny of Shahiwal, Sindhi, Haryana or other well defined bulls, yield atleast twice as much milk as the non-descript dam. The second cross shows a further increase in the production of milk.

Considerable amount of cross-breeding using imported bulls, has been carried out during the last 50 years. In the earlier years, the breeds favoured in India were the Ayreshier. A large number of Friesians were later imported which are reported to have given best results. The Indian Friesian yields on an average 4000 Kg of milk per lactation as compared to 5000 Kg given by Friesian cows. The Friesians are regular calvers, their productivity, however, is dependent on the care and attention given to them. These are maintained in favourable areas and moved to the hills in summer. The yield goes down as the percentage of Friesian blood is increased or decreased. It has been found that an increase in the production of Friesian blood increases the capacity to produce but the constitution of animal is not equal to the strain imposed in producing the milk to capacity. Although cross-breeding with foreign breeds improves the milk production, it is not widely adopted as the animals need expert care and management, not usually given to cattle in India. Experience shows that the cow produced by repeatedly back-crossing the half-bred is superior to the cow started with. For more effective utilization of limited number of breeding bulls now available, artificial insemination has been introduced throughout the country. In the very beginning the artificial insemination was followed at regional research centers in Calcutta, Patna, Montgomery, Bangalore and Izatnagar.

For establishing a good goat farm, a beginning can be made by taking a few good milch-yielding mother breeds with their male and female kids. After making a beginning with small

number, in about a couple of years, it would be possible to sort out best milk yielding mothers and those not needed for participating in the breeding programme, may be castrated at the age of 3 to 4 months and may be disposed off at the appropriate time.

Feeding Stuffs

The feeding stuff for dairy cattle may be broadly classified into roughages and concentrates. The roughages consist of succulent feeds (natural grazing, cultivated grasses, cultivated fodders and root crops) and dry fodders (hay, straw, chaff). The concentrates consist of carbohydrates-rich materials (oil seed, oil seed cake and meals). In addition to roughages and concentrates, dairy animals also require a certain amount of common salt to keep them in good condition.

Investigations in this area show that a number of materials hitherto considered as wastes, can be utilized as cattle feed eg. mango seed, jaman seed, and mahuaflowers (concentrates) and ground nut husk, bajra and coffee husk (roughages). In addition to distillary products (malt sprout, millets and molasses) feeds of animal origin eg. fish meal, blood meal and bone meal may be employed as cattle feed. The table below gives information about the feeding stuff, commonly fed to dairy cattle in India.

Dry rough ages	Green fodder	Concentrates
Wheat straw	Maize	Gram
Oat hay	Lucerne	Bran
Rice straw	Berseem	Cotton seed
Maize stalks	Oat	Cotton seed cake
J u war stalks	Juwar	Mustard cake
Legume straw	Bajra	Linseed cake
Grass hay	Elephant grass	Til.cake
Bajra stalks		Ground nut cake
Berseem hay		

6.4 DAIRY

Milk is produced by the mammary glands which are specialised skin glands. The actual secretion of milk by the mother is stimulated at birth by a lactogenic hormone (galactogen or prolactin) which comes from pituitary gland located at the bottom of brain, adrenal hormones also are essential for lactation. During gestation, the production of lactogenic hormone from pituitary is inhibited by the presence of another hormone, estrogen which disappears at birth. In some mammals the stimulus of sucking offspring serves, through the nervous system, to stimulate the secretion of lactogen.

Marketing and distribution

In urban areas 60 to 70 percent of the total milk requirements is produced within the municipal limits, the rest is obtained from adjoining rural areas.

Only 6 to 8 per cent of the total milk produced in the country is transported from rural to urban centres for consumption as milk and milk products. Nearly 2/3rd of milk received from outside the municipal limits comes from within 8 to 15 kilometres of the towns, and the remaining 1/3rd from beyond this distance. A part of the milk consumed in large cities, like Calcutta, Mumbai, Chennai, Delhi and others, it is obtained from localities situated at a distance of even 75 kilometres. Some successful efforts have been made to organize the production and marketing of milk on a cooperative basis.

Prices

The price of milk varies to a great extent from place to place. In rural areas there is practically no good market facility for fluid milk. The milk leftover after meeting the demands of the producer's family is converted into butter, ghee or khoa. These products are sold at weekly markets at prices largely determined by the distance of the market from the village. As a rule, cow milk is cheaper than buffalo milk but it may not be true for all the time and for all the places.

Milk Products

A variety of milk products is known in India and some of them figure in interstate trade. Dairy products such as cheese, butter, condensed milk, milk powder, curd etc. make the dairy farming a highly attractive industry.

Dahi (Curd)

It is prepared by souring milk with a lactic acid starter which is usually curd of the previous day. For the preparation of curd, milk is first boiled and cooled from 60 to 70°F. Further, starter is added and is kept untouched. Thus, curd becomes ready for consumption in 10 to 12 hours. Curd contains 0.6 to 1.0 per cent titratable acid expressed as lactic acid. It has a lactic flavour and a compact smooth texture. Its composition varies with the quality of milk used, the types of organisms present in the starter and the time allowed for souring. The organisms present in the curd are mainly streptococci (*Streptococcus thermophilus*) and *Lactobacillus casei*. Curd is normally consumed at the place of production. Curd contains 84.79% water, 7.7% fat, 3.4% protein, 4.6% lactose, 0.7 to 0.8% lactic acid, 0.7% minerals, 0.12% calcium and 0.95% phosphorus.

Cream

Cream is a fat containing fraction separated from milk by centrifuging the liquid milk. The separator, commonly employed, consists of a bowl with a large number of conical discs arranged one above the other with intervening spaces. Milk enters through an opening in the centre and as the bowl is rotated, 3,000 to 20,000 rpm, the lighter fraction which is cream, is driven towards the centre and the heavier fraction or skimmed milk is drawn towards the periphery and drawn out.

The second method to obtain the cream is the gravitational method in which milk is kept in a container at 50°F. After 24 hours cream automatically comes on the surface of the milk which is taken out by spoon. The yield and quality of cream vary according to the quality of milk and to the speed of separator. Skimmed milk is obtained as a by-product which contains 0.04 to 0.5% fat and is used in the manufacture of condensed milk, milk powder, butter, milk and cheese. The yield of cream is about 10% from a buffalo milk, 6% from cow milk and 7.5% from mixed milk. The composition of cream is 56% fat, 1.6% protein, 3% lactose, 0.4% minerals and 39% water.

Butter

Butter is a mixture of milk fat, butter milk and water. Salt and colouring materials are often added. It is good source of vitamin A and fair source of vitamin D. Butter is characterized by spread ability, a characteristic not found in butter substitutes. This probably is due to the glyceride structure of butter fat and to the presence of lower saturated fatty acids.

Desibutter or makhkhan is prepared by churning curd after dilution with water, in earthen or tinned metal pots by a wooden pole to one end of which beaters are attached which is known as "mathani". The butter usually contains 18 to 25% water and varying quantities of curd. The composition of butter is 14% water, 83.5% fat, 1.5% lactose, 0.3% minerals and 0.8% aluminium.

Creamy butter

The production of creamy butter in India is confined to few dairies. For the preparation of creamy buter, cream is aerated and ripened at 75 to 95°F to develop the desired smell and to facilitate churning. The ripening is effected usually by the addition of natural starter such as curd, fermented cream and butter milk or commercial starters containing pure cultures of lactic acid bacteria. The ripened cream, after dilution with cold water is mixed with a small quantity of dye and then churning is started at temperature 50 to 60°F. Churning is usually carried out in the mornings, when temperature is low otherwise ice is added to maintain the desired temperature. The whole operation takes 30 to 40 minutes. Butter milk is drained off and the butter is washed repeatedly with cold water. It is then salted, up to 2.5%, by adding salt solution either in the churn or after taking out the butter. Excess of moisture is pressed out to give a product with a firm and compact texture.

Ghee

Ghee or clarified butter is obtained from butter by eliminating water. It is next to milk in importance as a dairy product. It can be stored over long periods and for this reason it is preferred in comparison to butter in most of the tropical countries for comon people. Ghee is produced in India according to the traditional process involving sour curding of milk, recovering butter and heating the butter to remove water. Desi butter is preferred to creamy butter as ghee obtained from the former is melted into ghee at once or after storage upto 10 days. It may be partially dehydrated and later converted into ghee according to the demand of market. The temperature employed for clarifying butter varies from 80 to 125°C. Short exposure to 120°C does not interfere with the formation of grain nor does it diminish the

carotene and vitamin A contents of the ghee. To ensure proper grain formation, the tins to which ghee is transferred should be kept undisturbed and cooling should be allowed to take place gradually. The appearance of colour and grain structure influences its market value. The ghee of cow is yellow and that of buffalo is whitish. The grain in buffalo ghee is bigger than that of cow ghee. The composition of ghee varies according to the composition of the milk from which it is derived. Ghee is mainly used for cooking, frying and taking directly with the food materials. Ghee is subjected to extensive adulteration in the trade.

Malai

When milk is heated, a layer of fat and coagulated proteins, malai, is formed on the surface. Slow heating helps to increase the thickness of the layer. The volume of malai can be increased by boiling the milk until a voluminous froth is formed and cooling slowly over a dying fire. Malai is either consumed directly, or used in the preparation of sweets. Its composition is moisture 60 to 70%, fat 25 to 30%, proteins 3 to 3.5%, lactose 3.3 to 3.8% and ash 0.4 to 0.5%.

Condensed milk It is obtained by evaporating milk at 130 to 135°C in a vacuum p:m to the required concentration. The concentrate is homogenized to prevent the separation of fat, cooled and fortified if necessary. Stabilizers such as disodium hydrogen phosphate or calcium chloride, are added to prevent coagulation during the sterilization. The condensed product is cooled rapidly from 80-86°F and held at that temperature for 15 to 20 minutes. The cooling is so controlled that the crystals are of small dimensions and remain in suspension in the viscous liquid.

Khoa

It is prepared by the rapid evaporation of water from the milk. It is usually prepared from buffalo milk by heating with brisk stirring in flat-bottomed shallow steel pots until the volume is reduced to about one-fifth. The product is gathered in a compact mass, cooled, and packed for markets.

Alum is sometimes added to the milk during the boiling to give a smooth texture to the product. Khoa is consumed directly or used as an ingredient of sweets. It can be kept for 3 to 4 days without deterioration. The common adulterants of khoa are cereal flours.

Cheese

Cheese is the product made from the curd, obtained from whole or skimmed milk with or without added cream by coagulating the casein, and then further the separated curd is treated by ripening ferments. Soft cheese, known as 'Paneer' is prepared by using coagulants as the source of coagulating enzyme for clotting milk. Milk is warmed to about 100°F and the crushed coagulants are tied in cloth and dipped in it. The milk curdles in 30 to 40 minutes. The coagulum is placed on a muslin cloth and the whey is drained out. The process of cheese manufacture varies very much but not to such an extent as may be with different characters of the final product.

Future prospects

The present retail prices of milk in urban areas in India are higher than those in the other countries. This is due, principally, to inadequate supply of milk. With a view to increase the per capita consumption of milk, the Planning Commission has suggested the adoption of measures for raising milk production in suburban areas. Emphasis has been laid on the need for maintaining hygienic conditions during the collection, transportation and distribution of milk and for enforcing measures of quality control.

The setting up of a statutory milk board for each urban area, consisting of representatives of producers, distributors, consumers, Municipal Corporation. Health authorities and the state Governments is a good initiative from Planning Commission. The matters related to the handling, distribution, quality control, imports and price of milk, and milk products come under the jurisdiction of the board. The financial assistance needed will be provided by government, municipalities and cooperative banks. Village schemes have been formulated for improving the breeds of milk cattle and for ensuring adequate fodder supplied for dairy cattle.

6.5 LEATHER INDUSTRY

Since the dawn of civilization man had started the use of animal skin to wrap his body before the invention and knowledge of clothes. Today, when a number of synthetic fibres and other materials are under use, the position of hides and skins in the world market is increasing day-by-day, of course, for different purposes. The skin of a number of mammals is being used for the preparation of clothings, attaches, purses, shoes, belts, etc. after proper tanning. Out of the total production of leather in India, 86-7% is obtained from the hides of dead animals and

a very little quantity *i.e.*, 13.3% from the slaughtered animals. The livestock population in India is highest in comparison to that of any other country in the world as such the production and status of skin and hide industries in India is on the top in the world. Yet due to the lack of proper technology and low grade tanning process it has so far never been possible to compete in the world market particularly regarding the quality of leather. Thus there is an urgent need for proper tanning of skin in this industry.

Animals of Leather Industry:

The principal animals in this industry are goat, sheep, cow, buffalo, lamb, snakes, lizards, tigers, crocodiles, varanus, etc. The skin of cow is called as 'kips' and that of the buffaloes as 'buffs'. The cow hides are available from Tamilnadu, Uttar Pradesh, West Bengal, Kerala, Madhya Pradesh, Bihar, Maharashtra and Orissa since long but now-a-days only Kerala and Bengal are producing cow skins. The goat skins are common from Uttar Pradesh, Bihar, Rajasthan, West Bengal, Madhya Pradesh, Mumbai, Chennai and Hyderabad.

Processing of Skin Industry :

To obtain the leather from skin and hides is a long and complicated process. The states where the cow slaughter is banned by State Government, only fallen animals are used to get hides, whereas, in other States like West Bengal and Kerala leather is obtained from the skin of slaughtered and fallen animals both.

Flaying

The traditional job of flaying has been taken by the hereditary flayers in villages. During the process of flaying some amount of flesh and fat tissues remain attached to the hide due to which the weight of hide increases. To minimize the knife cut on the hide it is essential to have flesh and tissues with it. The carcass is hanged with a pole with the hind limb upward and flayer pulls down the hide over the back of dead animals with his left hand. Now the hide undergoes further processing or curing.

Curing

Due to the atmospheric temperature and presence of bacteria and humidity, the hides containing flesh and other tissues start decaying just after flaying. Therefore, the swelling of skin occurs within 12 hours after flaying. The bacterial action causes the liquification of the

flesh and fat tissues but this bacterial action must be prevented by the use of antibacterial agents.

Salting

The cured skin is now placed for salt treatment. The common salts used for this purpose are sodium sulphate, sodium chloride (common salt), potassium nitrate etc. The salting is performed by spraying the powdered salts on the fleshy surface of the hide. Now the salt treated skin is ready for being sent to factories for tanning.

Tanning

The tanning of skin is an ancient art in India, and was being practised before Christian Era. Before the war of independence of 1857 tanning was mostly confined to the villages but after that in 1867, British Government established 'The Government Harness and Saddley Factory' at Kanpur. Only vegetable tanned leather was produced based on the technology taken from England. Another factory 'Copper, Allen and Company' was set at Agra and Kanpur to produce the same leather. The chrome tanning was started in the Government Schools of Chennai, Calcutta and Kanpur as a subject. The first chrome tannery was established in Chennai in 1903.

2. Pre tanning.

The pre tanning process consists of a number of steps viz, soaking, liming, unhearing, fleshing and scudding, deliming, pickling. The pickled skins and hides are treated with organic, inorganic and synthetic' tanning agents like basic chromium sulphate; basic salts of aluminium, zirconium, and iron; formaldehyde; quinone; aliphatic sulphonylchloride, fish oil and synthetic polymerized materials (syntants).

3. Post tanning

After proper tanning the skin is subjected to a number of mechanical, physical as well as chemical processes viz., removal of water and tan liquor, splitting and shaving, neutralizing, bleaching and dyeing, setting out, samming, drying, staking, buffing and finishing to provide the fancy touch to leather for commercial grace.

Number of public and private sector producing leather and leather goods are:

1. Cooper, Allen and Company, Kanpur.
2. Cawnpore Tannery Limited, Kanpur.

3. Shewan Tanner, Kanpur.
4. United Provinces Tannery Company Limited, Kanpur.
5. DayalbaghTaj Tanneries Limited, Agra.
6. Bata Shoe Company Limited, Batanagar andMokama.
7. National Tannery Company Limited, Calcutta.
8. Chrome Leather Company Limited, Chromepet, Chennai.
9. Government Tannery Phulbani, Orissa.
10. Gordon, Woodroffe Leather Manufacturing Company Limited, Pallavaram, Chennai.
11. Mysore Chrome Tanneries, Bangalore.
12. Western India Tannery Limited, Mumbai.
13. Gold Filled Leather Works, Mumbai.

Enemies of skin industry:

The skin industry also suffers from its enemies like warble-fly and tick. Warble fly makes a number of holes on the hides and skins due to which its value decreases from commercial point of view. If the attack is severe, the products are made useless for any commercial purpose. In previous decade 25,000 goat skins, exported to U.S.A. from Kanpur, were severely attacked by warblefliesresulting in the loss of about 100,000 rupees. Ticks are also found damaging the skins and hides. The ticks cause about 20 to 30 per cent damage of the whole stock of skins and hides in Punjab, Uttar Pradesh and Rajasthan.

Recent efforts

The Government of India established "All India Khadi and Village Industries Bored in 1953 and entrusted the job of looking after the proper processing and utilization of hides. and skins. This board manages the production of a number of skin articles in which about 2 million workers are actively engaged in India, The small scale industries produce about 70 per cent of the skin products. In the Central Leather Research Institute (CLRI), Chennai, scientists are actively engaged to improve the quality of leather by modern techniques of leather processing. In U.P. 'The Uttar Pradesh Leather Development Corporation' (UPLDC) has been recently established for encouraging the leather industry. Recently UPLDC has sanctioned for starting a factory in Basti district at a cost of about fifty lacs.

6.6 WOOL & FUR INDUSTRY

The wool yielding sheeps are inhabiting the arid regions of Northern India specially in plains as well as in the hills. The important places *viz.*, Saurashtra, North Gujarat, Kutch, Kashmir and the foot hill districts of Himachal Pradesh and Garhwal are most favourable for providing the natural conditions suitable for raising fine woollen types of sheep. The largest sheep population has been recorded at plateau of Deccan and Vindhya Mountains. The wool obtained from the sheep of Kashmir is finer in comparison to that of other places. The Magra and Chokla is the best breeds from Bikaner, and Kutchi from Joria (Rajasthan) which are famous for the superior type of carpet wools.

Types of Wool in India

The proper and systematic classification of wool with regard to its quality is not yet properly known but it is classified according to the territorial nomenclature as given here under:

Wool type	Colour
Joria	Superior white
Harmal	White grey
Bikaneri	Super white
Rajputana	Yellow grey
Bibrik	White grey
Marwar	Yellow grey
Vicanere	Skin wool/Common black

Physical Properties

The colour of the wool varies from species to species of the sheep and also the climatic conditions of the area. The real wool fibre is hygroscopic, elastic, durable, bad conductor of heat and is not easily inflammable. Due to its nature (bad conductor of heat) more heat is produced when the wool is wet. The microscopic study of the wool fiber seems to have cellular structure. In the transverse section of the wool fiber two regions are distinguishable *i.e.*, a central core of hard cells in the periphery and a medulla somewhat softer, situated in the centre. The affinity of wool to dye absorption and the easy twist are the characteristic features of pure wool. The diameter of the wool fiber has been noticed to be 12 to 80 μ . The

wool produced in India has a remarkable property of regaining the original shape when pulled and has abradable resistance.

Chemical Properties

The wool fiber is made up of keratins which are actually, the polymers of the proteins and have higher sulphur contents. It consists of a number of polypeptide chains of amino acids. The various amino acids which constitute the wool protein are: arginine, histidine, lysine, alanine, methionine, threonine, tyrosine, cystine, leucine, iso-leucine and valine.

Removal and Wool from Sheep

The shearing of wool is essential to promote the health of sheep. It also provides protection from natural enemies' viz., ticks and mites which infect the sheep and cause various diseases. The removal of hairs from the sheep should be done carefully in the mild weather. The recommended periods for shearing of wool are winter (February to March) and rainy (August to September) seasons when rich grazing ground is available. Before the removal of hairs the sheep should be washed properly. The sharpened shears must be used for shearing purposes.

Processing of Wool Manufacture

The manufacture of wool from sheep hairs is a complicated process consisting of cleaning, drying, bleaching, dyeing and twining.

Cleaning First of all wool obtained from sheep should be washed with cold water in specially constructed water tanks. After washing, the wool should be pulled out from the tank for further processing.

Drying The properly washed wool should be kept in open sun for drying for two to three days.

Bleaching The well dried wool would always be of faint and rough colour, therefore, it is essential to bleach it properly. The bleaching should be done by a number of physical processes because the chemicals destroy the wool in this condition.

Dyeing The bleached wool absorbs any dye rapidly so care should be taken that the amount of dye and the dyeing period is accurate.

Spinning and twisting Now the coloured wool is sent to mills for spinning and twisting. The spinning and twisting of wool is performed by a number of devices which varies from region to region. The shepherds use the spinning wheels to make the thread.

Recent Efforts

The management of wool production in India has been unplanned since long with the result that the persons who are engaged in wool production are not getting proper price. The Indian Council of Agricultural Research, New Delhi has taken over the management of wool production and trading since 1937 and has appointed an authority, 'Sheep and Wool Development Officer' to control the whole production as well as the sale of the wool. The annual budget regarding the wool production is prepared by the officer and sent to the Govt. of India. The annual production of wool by different states has been recorded to be maximum from Rajasthan. The other states come on the position (production-wise) as : Rajasthan > Uttar Pradesh > Punjab > Gujarat > Andhra Pradesh > Tamil Nadu > Maharashtra > Karnataka > Jammu and Kashmir > Himachal Pradesh > Bihar.

Fur and Fur Industry

The word fur is derived from old French word *forre* and *juene* meaning a 'sheath' or 'covering'. Fur is what may be described as the soft 'down' dense growth of fibres (small hairs) covering the skin of certain animals (mammals). Fur bearing animals also have a covering of longer hairs called as 'guard' hairs or over hairs which protect the underlying fur from injury and prevent-it from matting or falting. Thus there is difference between 'fur' and 'hair' although both protect the animal from cold and storm.

The chief needs of the primitive man in the colder regions of the earth were food and warmth and it is quite reasonable to assume that the use of animal flesh for food from that of animals' fur for warmth was not long separated. Thus the practice of wearing fur is as old as humanity and obviously it outdates the art of spinning and weaving. Necessity came first but luxury soon followed, and the utilitarian and the beautiful marched side by side from remote antiquity into the present day. It is no more an article of clothing but now of luxury and decoration. This is why furs have tremendous fascination for woman kind and she assumes her 'furs' when she wishes to impress, not merely when she is desirous of keeping warm.

Assyrians, Romans and Greeks all, made lavish use of furs. It is recorded that Herodotus, and queen Samitamis (2182 B.C.) brought 8000 tiger skins from an Indian campaign. Some of these skins were put as uniforms for the royal house hold troops. In the time of Homer (850 B.C.), Armenia was the centre of a large fur trade and skins were coming from Siberia, Russia, Persia, Bokhara and even from far away places for distribution in Europe and elsewhere. The use of fur gradually became popular mainly with the royal family particularly the ladies in the various countries. The man did the hunting and fighting and the ladies adorned themselves, with the furs. Prof. Blach has mentioned: "Man must ever slave and toil, that vanity may wear the spoil". The woman has achieved equality rather superiority with regard to wearing of fur. There was a gorgeous display of furs at the coronation of Queen Victoria. The wearing of furs today is practically universal among the fair sex in all the civilized countries where the temperature warrants it and frequently when it does not.

Valuable furs are obtained from those regions where the winter temperatures is low and the growth of the fur on animals is thick and luxurient. It is a fact that 'the colder the climate, the better the fur'. Canada, North America, Northern Europe and Siberia are among the important countries which supply fur. Himalayan districts also produce a certain number of large fur bearers, such as leopard, snow leopard, snow lynx, and tiger.

An immense organisation is necessary in this trade which is a most hazardous game, and many fortunes have been lost especially owing to sudden changes in fashion. There is an old saying, 'Furs when wanted are diamonds, when not wanted, charcoal'. The retailers atleast live and prosper or fail under civilized conditions, but the man at the other end of the trade, in some cases thousands of kilometres away, who actually gets the skin *i.e.* the hunter is usually a combination of both. The hunter has to face death from cold, starvation, fatigue or even at the teeth and claws of the denziensof the wild. They have to face the sand storms of the desert or the blizzards of the Arctic. At the end of the chain is the hunter, striving against the most terrific hardships that can be conceived and at the other, the designer.

Hudson bay to all intents and purposes is the true centre of the hunting grounds. It is ice-locked for nearly eight months every year. Skilled men are needed to get the precious skins from regions, difficult in transport facilities and where even rivers are frozen. In the more northern regions, extending uptoand beyond the Arctic circle, the fur trade depends to a large extent on Easkimos. After trapping, the animals are slaughtered and cut there at the collection

base and then the skins and the blubber conveyed to the nearest camp and thence dog-siege or taken by other means to a fur company outpost.

Dressing

Technical and artistic skill of high order is required to get the raw skin manufactured. The first process through which they go is that of 'dressing' (curing). To dress a skin implies changing it from somewhat raw state to a condition of softness, indescence and beauty. The function of the fur skin dresser is to make the skin suitable for the use in the later stages of the trade.

The art of dressing skins has been known in some form or the other from very early days. Probably Chinese discovered alum as a best preservative and they claim to have made use of fur for 3000 years. Thus their mode of dressing skins continued for centuries. The procedure varies widely somewhat according to the nature and condition of the skin treated but in every instance there are at least four distinct stages.

1. The preliminary cleaning and softening of the pelt.
2. The fleshing: The removal of fleshy matter and blubber from the skin.
3. The leathering: Formation of leather on the skin which is actually a form of tanning.
4. Lastly the final cleaning.

It would be worthwhile to describe a simple and almost common process for dressing the skin.

1. The skins are first soaked in salt water for twelve hours if the weather is very hot and for twenty four hours if cool. Then it is conveyed to a *centrifugal* machine which *rotating* at a terrific speed clears away *the superfluous* moisture.
2. The fur is neat cleaned with benzine and then sent to the unhairer.
3. This craftsman (unhairer) after thoroughly warming the skin stretches it over rounded wooden block and with a blunt, two handled, sickle-shaped knife presses strongly with a dragging action, on the fur for pulling out the rough hair by the root, and leaving the soft fur or down untouched. This process may have to be repeated thrice or four times for removing all the top hairs.
4. The skins next go to the drums (a gigantic wooden cylinder) filled with dry saw dust or other suitable material. The drum is rotated for an hour or more, the saw dust by this means being forced into the fur and further cleaning takes places.

5. The skins from the drum are put into tanks containing ordinary fresh water and soak there overnight.
6. It then goes to the flesher for shaving off all the remains of the fat or grease. In this process the flesher runs the skin with a drawing motion over the edge of a very large knife tied in a vertical position. In some cases the skins are fixed and the knives are run.
7. After this the skins are hung up in a hot room preferably between 120° and 130°F. In this chamber the skins get thoroughly dried and at the same time, get hard once more.
8. Again the skin is put on the drum but this time for the purpose of being broken down *i.e.* made flexible, and when the desired flexibility is reached, this process is stopped.
9. The leather side is then thickly covered with grease which is spread evenly.
10. The skins are then folded up, greased inside and put in a huge tub where a person (or persons) treads them steadily for a varying period. It is this process which is known as leathering. The treader is a skilled worker and he should know when to stop this process. If in treading insufficient time is given the skin will not leather properly but in patches. On the otherhand
if it has been done for a longer period the hair will mat and the skin will be spoilt.
11. However coarser skins are 'trampled' in a machine which is double wooden pistons working in troughs.
12. Lastly the skins are turned to the fur side and are thoroughly rubbed with saw dust, then to the drum where the saw dust may be changed six times before they are finally cleaned.

After each drumming the saw dust is removed completely from the skin either by beating with hand or other kind of drums, sometimes termed as 'cage' whilst the fur comb is constantly used.

Although the process of dressing originated in a primitive and haphazard' manner, the modern fur skin dressing is a highly developed scientific process requiring, incidentally, considerable mechanical equipment.

The skins thus dressed are known as furs and ready for grading which is done by the assorter who is a skilled and highly paid person.

Dyeing

In early days the dyeing of the furs was mainly carried out with the negotable or mineral colouring matters. The modern development in dyeing took place from the latter part of the 19th century. Many chemical compounds known as fur bases have been developed. The whole process was revolutionized by the discovery of aniline dyes by Sir W.H. Perkin, an Englishman. The use of synthetic compounds as dyes has opened a new era for the production of many new colours on furs.

On the technical side of dyeing great secrecy is maintained. Each dyer jealously guards his methods from competition as thousands of experiments are made before really satisfactory dye process is evolved. Huge amount of literature is available on the dyeing industry. The importance of fur dyeing increased in the 1950s and new colour became an important selling point among fur retailers. From traditional browns and blacks of natural colours different shades depending on the fashion of the day and the liking of the people were developed. Different countries excel in different dyes. The chief dyeing centres of Europe are France, Belgium and London. At one time Leipzig was supreme in this field but later on Frankfurt, London and New York became important. U.S.A. has developed resin as a formidable competitor and New York has the largest fur processing industry.

Dyeing by dipping and brushing; cleaning the leather by repeatedly passing over a revolving emery wheel, and removing any top hairs left after unhairing is a highly ingenious process. Topping is a favoured process among the furriers. It means artistically and lightly brushing the top hairs with the dye, so that a badly marked skin be provided with rich colouring as is found on a good quality specimen. Topping is also done to fresher up partly worn skins which assume perfectly new appearance after going through this process. In U.S.A. a chemical process for straightening the curly fleece of yearling lamb skins has been developed. After undergoing this process the product is known as 'Mouton' which is used for aviators coats, bed room slippers and coat linings. It is durable and the fibers stay straight. They are resistant to moisture and can be easily cleaned.

Fur Manufacturing

The making of fur into garments technically designated as 'Furriery' has progressed to a great extent. From the primitive stage of sewing it has now become a highly skilled and intricate

occupation because of the advancement in fashions. Paris is famous for originating fur fashions, then Italian designers are also well known. At present New York is the largest manufacturing centre. The persons involved in the trade are, designers, cutters and sewers which are all highly technical jobs. Formerly sewing was done by hand but today highly efficient fur sewing machines do the work. Liners and finishers then complete the job.

There are two main types of fur manufacture. The first one is known as the letting out technique in which every skin is sliced into diagonal strips of .5 to 1.5 cm in width and then sewing these strips together, thus making longer and narrower strips without showing seams on the fur side. The other skin-on-skin method is less costly. In this case .one full skin is sewed adjacent to another in an uniform alignment. Some firms get the left overs of full skins and specialize in sewing them in the form of blanket like plates.

Caring for Furs

Great care should be taken in keeping and maintainance of the fur and fur garments. It should be remembered that even a little care taken of these beautiful and usually costly articles of wearing is well repaid thousand fold. Some of the suggestions in short are :

1. Keeps the fur hanging upward in darkness.
2. Before putting them on and also when taking them out, give them a shake. Shake them with the floke of the fur *i.e.* from the head.
3. Beat them occassionally with a light care gently.
4. Comb them gently but frequently with a fur comb.
5. If the fur gets wet never dry them in front of a fire or strong sun but hang them up in a room in a drought preferably. In this way it will dry gradually and when the moisture is gone, shake them well and comb.
6. The worst enemy of the furrier as well as the keeper of the fur garment is the 'Moth' which causes havoc. It is the grub of the moth which is responsible for the damage. The insect shelters in the fur and lays its eggs at the roots of the hairs. When eggs hatch, the grubs attack the roots and thus the hairs fall and large bare patches appear. (a) The whole stock, if possible, should be kept in cold storage, (b) Beating with light cane is most effective in this case also. (c) Pepper, campher and nephthaline can be used.

By-products

Fur cuttings and guard hairs are by-products of the fur industry. They are used in the manufacture of fabrics. Inferior grades are used as fertilizers and for glue stock.

Fur bearing animals

The principal fur bearing animals of the World belong to the order Carnivora of the class mammalia. The other fur bearing groups are Rodentia, Ungulate and Marsupialia. Some insectivora like moles and others also provide fur but they are not important from commercial point of view.

In India the number of fur bearing animals is small and restricted almost entirely to the Himalayan region. The animals in other parts of the country possess relatively coarse hair. During the British period in India, animals such as leopard, snow leopard, snow lynx and tiger were hunted by Gurkhas and the skin purchased by Indian merchants operating from Almora whilst the bulk of the central Asiatic fur were despatched by Camel, donkey and bullock transport to Peshawar and then by rail to Mumbai from where they were shipped to London and New York.

In a limited space of this book it would not be possible to give a description of all the fur bearing animals, but a few facts on the more important species should serve the necessary purpose.

1. Badger (Lat. *meles*, Fr. *Blaireau*,) This animal is to be found in both the old and the New World. In Russia, the hairs were used- for shaving brushes. All badgers have a peculiar white marking on the head and back. It is nocturnal and carnivorous. The American badger produces the best fur, the Chinese and the Japanese are coarse and inferior in texture.

2. Bear (Lat. *Ursus*, Fr. *Ours*) four kinds of bear are in common use in the fur trade *i.e.* Black, Brown, Grizzly and White. The largest is the polar bear the skin of which has even touched 3 metre in length and weighing about 500 to 800 lb. The Eskimos are very much fond of bear meat and are stated to kill the animal in an interesting but shrewd manner. The 'grizzly' bear (Lat. *Ursus horribilis*- grisly bear) 'known to hunters as 'uncle Eph' is the most formidable to the tribe. It is 2.5 metre long and reputed to be very cunning and armed with claws 10-15 cm in length. The name 'grizzly' denotes the colour of the fur which varies from pale grey to brown grey. To wear the collar of the grizzly claws denotes that the person has killed the bear single handed. This fur 'is mostly employed in the manufacture of motor and

floor rugs. The brown bear is a synonym of the Russian bear which in addition to Russia is found all over Europe. The dancing bears are of the brown and black variety.

3. Beaver The animal is from 30 to 90 cm in length and has a tail which resembles a paddle. The fur is of chestnut shade. It is found in Canada, Russia, Norway and also U.S.A.

4. Chinchilla A native of South America, is a small squirrel like land rodent. The fur is extremely beautiful slate grey with delicate dark markings and the leather is almost as thin, as tissue paper. The animal varies from 20 to 25 cm in length and is a Vegetarian.

5. Ermine: It is probably the most celebrated fur in the world. Ermine fur is really the winter dress of the Stoat which is an animal of the weasel tribe belonging to Carnivora. It is 25 cm in length and most ferocious blood thirsty, savage and cruel. A peculiarity in this animal is the great change that takes place in their natural covering on the approach of winter. It is light brown in summer which becomes white on the arrival of winter with the exception of the tip of the tail which always remains black. It is good and hard wearing fur, but prone to be yellow with the passage of time. It is used as a garment for children and well to do persons and also as a trimming to furs of different animals.

6. Fisher It is a mammal and it does not fish and is a type of large weasel which is about 60 to 90 cm long. It is very swift in its movements and is supposed to attack and eat the percupines also. Fur is rich dark brown and the long, hairs are practically black.

This creature inhabits Canada, certain parts of United States and parts of Northern India.

7. Fox There are numerous varieties of fox in common use in the fur trade. A passing mention may be made here of the principal ones. They are found all over the world. They range in colour from pure white to almost equally pure black with numerous grey, red and blue varieties. Pure black fox is both rare and expensive. The usually seen black fox skin is a red or white dyed to black. The different varieties are:

(a) **Blue fox** This is not blue but rather of a slate colour. It is small not very plentiful, and hence costly.

(b) **Cross fox** This is handsome rather flamboyant skin and a variety of American red fox. It is generally of a yellow or orange tone.

(c) **Grey fox** It is also known as virginia fox and is handsome, about 75 cm in length.

(d) **Patagonian fox** It is from South America and resembles a jackal rather than a fox.

(e) **Redfox.** This animal inhabits both the old and the new World (Europe, U.S.A., Canada and Asia). The American variety is most popular in fur trade. In colour it is reddish brown. Feeds chiefly on rabbits and is an enemy of poultry farmer. The colouring and quality of the fur vary to a great extent.

(f) **Australian fox.** The fur coming from the sub-tropical climate is of poor quality.

(g) **Silver fox.** It is the king of foxes from the point of view of beauty. The skins are by far most expensive of the fox species and vary in colour from all black to all silver. This fox will further be described under 'fur farming'.

(h) **White fox.** It is found in the Arctic region and usually on the sea shore. It is a small animal of about 60 cm and gregarious rather or migratory disposition. It turns snow white in winter only. The skin is of singular beauty and quite devoid of smell.

8. Lamb. They are found almost all over the World. The fur is extremely popular, being both handsome and hard wearing. It is used for every purpose to which the fur IS put. The best lamb skins, silky with tight curl and fine glass, undoubtedly come from Bokhara, whilst others of inferior quality are obtained from Afganistan, India, Persia, Asia and Rumania.

9. Leopard. This animal and the panther are considered to be of the same species and found distributed freely over the whole of Asia and Africa. The skins make handsome rugs. The bass drummer uses the skin as an apron.

10. Marten. There are four martens in common use in the fur trade viz .thebaum, stone, Japanese and American or Canadian. It varies from 45 to 60 cm in length. It is arboreal, greedy and extremely active animal. Its fur is silky, the best specimens, being of a rich dark brown colour and the inferior skins beings lighter and yellower. The darker the fur, the more valuable it becomes. Hence the paler martens are frequently dyed or 'topped'.

11. Mink. This is another savage animal of the weasel tribe. It inhabits Canada, U.S.A., Russia, China and Japan. In Canada it is one of the main fur bearing animals. It is about 45 cm long and spends as much time in the water as on land. The fur is close, dense and thick. The leather or the pelt is also thick and comparatively heavy. The colour varies from yellow to red but as a rule it is oak like brown. The hair is short and close and the under fur is usually dark brown. The fur is used as garments for both the sexes and is rather more popular in Canada and U.S.A. than in Europe.

12. Musquash This animal is found in a belt extending from Alaska to Virginia in addition to Southern States. It is one of the most important animals used in the fur trade. The skin varies from 15 to 30 cm in length. The fur is a chestnut brown, the belly part being white and the under fur bluish or bluish white. It is warm and durable, expensive and in great demand for coats and linings.

13. Opossum There are two distinct kinds, one American and the other Australian. In colour it is grey, the top hair being light grey and the under fur is a dirty white. The fur is of coarse quality.

14. Sable It is found in D.S.A., Canada, Japan and Russia. It was once ambition of every woman to possess a set of sables as it was available in large quantities, but the supply today is all too small.

15. Seals Broadly speaking seals are either hair seals or fur seals. The fur seals really a sea-lion is now sold very sparingly owing to the regulations framed to prevent its extinction. It is highly gregarious in nature. The fur is in its best condition in June and July. The price of the seal garments is prohibitive.

16. Tiger The best tigers come from Central Asia. The well known Bengal tiger, is richly market but very poorly furred whilst the Manchurian is often 5 to 8 cm deep in the fur and many times more expensive. They are used as rugs. The other animals which are used in the fur trade are Pitch-having pungent odour; Lynx, Mermot, mole, dog, monkey, rabbit, squirrel and wolf.

Fur Farming

Fur farming is one of the oldest of the occupations. The Chinese have fanned dogs, sheep and goats for countless centuries, utilizing the flesh for food and the skins for trade. If we term the sheep a fur bearing animal, it becomes the oldest form of farming in the world.

A number of animal-husbandry practices of live stock raising were adapted in fur farming also but some of the fur farm problems were specific to these wild species because of their being in confinement. This is why specific research became necessary for handling some of the animals.

Germany has fanned Corsican sheep in Harymountains and also extensive farming in silver fox for musquash and. beaver has been done. Soviets fur Syndicate is farming black and blue fox, deer and other animals. The farm on the Komandorsky Island is one of the most ancient in the World. The Canadian Govt. in collaboration with the Canadian National Silver Fox

breeders association established a research station as early as 1920 at Sumarside and the U.S.A. Govt. Started 'The United States fur animal experiment station' "at Saratoga Springs, New' York in 1923. The United States Govt, by 1940 was conducting research on fur animals in cooperation with the colleges and universities in the States of Wisconsin, New York, Pennsylvania, Washington and Alaska. In Canada several provinces are also doing fur animal research in addition to 'Prince Edward Island' the 'home of the industry'.

In Great Britain there are farms for silver fox, skunk, marten, mink, fitch, musquash and nutria. Mole farms are also very popular and lucrative. Similarly rabbit farming is popular. The Fur Board Ltd. is a controlling body of rabbit breeders. Chinchillas are farmed in Andes blue and silver foxes in Norway and rabbit, nutrie, marten, fitch, Opossum and skunk in France, Sweden and Denmark who also began similar research because of increasing importance of fur farming in their economy.

Some suggestions for establishing a fur farm are given here. There are many others which may not be possible to describe all in detail.

(1) The farm should be kept at a secluded and " quiet locality. Any thing that tends to irritate the animal be avoided.

(2) Only accustomed persons should visit the animals and that too when absolutely necessary. Strange faces have extremely bad effect.

(3) Proper food to their living be provided at fixed time. They must be well fed but never over fed.

Silver fox farming Out of all the animals fox farming is most popular. The breeding of silver foxes in captivity was started in 1894 on Prince Edward Island. At first it was carried with secrecy till a beautiful silver fox skin was sold at London at a very high price. The British Crown knighted Charles Dalton for this work. Charles and R.T. Oulton both Canadians were at one time considered to be pioneers in this field.

A silver fox in mutation of red fox in which the red colour is replaced by black. The white band on the guard hairs gives the silver effect. The early captured foxes were nearly black but by selective mating over a period of 20 years, the bright silver fox was produced in which the white bands were extremely wide and black was free from rusty brown, Pair mating was first deemed necessary, but finally polygamous mating became the practice.

Blue fox fanning

It is done principally in Norway. It is interesting to note that in Alaska, the entire island were based for this work and the foxes ran wild. Due to lack of controlled breeding, the whole business came to a stop by 1940s.

Mink ranching

These animals were produced in Captivity for their fur as early as 1866 but by 1930 they were produced in quantity. After the middle of twentieth, there were three times as many mutations as the dark, natural coloured mink. The mutation mink breeders association controlled the market strictly. The sexes are kept separately and the polygamous mating is the common practice.

Chinchilla rising

As mentioned early it was a native of South America. In early 1900s Chinchilla furs were obtained from trapped animals. Due to trapping there was scarcity hence an American M.P. Chapman started their farming. By mid 1950s more than 5 lacs of these animals were being kept in captivity in U.S.A. and Canada. By 1954, it became one of the biggest trades in fur.

Martens

It is an attractive and interesting forest fur animal. Attempts have been made to raise them in Captivity but have failed because of only about 15% to 20% of the females produce young ones. They breed in July and August. Twenty litters were obtained over several years at the United States Fur Experiment Station.

Rabbit skins from animals raised primarily for food have been extremely used in the fur trade from time to time. Very few rabbits were raised primarily for their fur.

The other fur animals such as Karakul and other breeds of sheep have been raised in Russia and other countries for hundred or more years. South-West Africa by 1950s was producing several million Persian lamb skins after many years of selective mating.

The raising of several other animals in Captivity was initiated and developed for selling on a promotional basis by 1950s, but it had not materialized commercially, because of the availability of skins from wild variety. The animals that have been described or mentioned earlier under 'Fur animals' have almost all been raised at sometimes or the other. It all depended on fashions and the finding of new striking colours. There is no doubt that even with the natural coloured animals, improvement can be made by selective mating that can give them greater fashion appeal. It is only the scarcity of the wild types that will be a contributing factor towards successful farming of those animals.

Fur Farming in India

In India the main commercial types of fur skins produced are lamb skins and kid skins. But the trade in the skins of wild animals is very limited.

Lamb skins

Various Karakul sheep were the first fur bearing animals to be put under farmirig. The lambs of these sheep have black or grey wool with tight curls. The quality of lamb skin depends on the variety of sheep from which it is obtained, the age of the lamb when slaughtered and also the nature of the curls. Lambs have to be slaughtered within a few days of their birth for obtaining good skin with very tight curl of fur. In India even the pregnant sheep are aborted to take out the lamb and skinned for getting high price. Lamb skins from South India are of inferior quality and major portion of them is used for preparing 'Astrakhan' caps. .

There are four grades of lamb skins-Moire, Nazakkcha, Guldar and Plain depending on the degree of curliness of the wool and the waves which the curls form. Moire is obtained from the premature lambs and is of best quality. Nazakkcha is obtained from the lambs killed within twenty four hours of their birth and the last two variety-Guldar and Plain from those animals which are killed within six to twelve day of birth. India imports lamb skins from Tibet.

Kid skins

Rajasthan and other dry areas in India provide skins of fairly good quality. Their prices are fixed according to the uniformity in the arrangement and alignment of skin hair, the quality of the hair and the size and colour of the skins. In this case also there are graded and the first quality is Moire, the second Surface Patterns and the third is designated as Plain. Moires are obtained from kids killed within two days and Surface Patterns within seven days of their birth. The rest come under the third quality. These skins are exported to France, U.K. and U.S.A. which is the chief buyer. They are cheap in comparison to the lamb skin.

Skin of other animals

The skins of many wild animals like marten (*Martesfoina*Enxl.) of Kashmir and eastern Himalayas 'snow leopard' (*Pantherapardus*Linn) of Kashmir, Tibet and Sikkim, and Himalayan marmot (*Marmotabobak*Muller) and long tailed marmot (*MarmotaCaudata*) of the Himalayas are reported, to be exported to some extent from Calcutta port. Tiger and deer skins are mostly used locally. Tibet and Nepal supply small quantities of skins to Kashmir, U.P. and West Bengal depending upon the requirement. The skins of tiger's panthers, lynxes, foxes, jackals, bears, mongooses, otters, squirrels, hares and deer are also collected but their demand in the foreign market is irregular.

Markets and Marketing

Profits made in the fur trade are not dependent on the occasional specimen skins collected but on the quantities coming a few at a time, gradually pile up in huge quantities and sold by auction or negotiation.

In the past, say thirties, London was the chief fur market but later on' St. Louis and New York became the chief centre. Under American stimulus the fur trade went mad and prices rose so high that at once time it looked that the fur could only be used by very rich persons. Presently the other countries involved in the trade are Russia, Germany and other European countries.

In India fur skins are obtained mainly from Punjab, Himachal Pradesh, Uttar Pradesh, Rajasthan, Delhi and Gujarat.

Major portion of the fur skin produced in India is exported to foreign countries; Delhi is the main market for the distribution of fur skins, handling even more than 75% of the total Indian supplies. The skins collected at Agra and Jaipur are also brought to Delhi. During the period of mid-August to mid-April more than 80% of the skin is collected and the rest during other months. As regards the local demands of lamb and kid skins, it is confined to furs of inferior quality. Fur skins of all types cured and tanned in India are used for gloves, ladies coats, caps and other fancy articles.

It may be pointed out that increasing demand for fur skins all over the world and the lure for high prices for them have led to the destruction of rather mere or less extinction of many fur bearing animals. At the same time the decrease in the supply of furs of high quality has made it costly and also created a demand for inferior furs. These days even artificial and synthetic

furs are being produced on a factory scale. One fact is also to be remembered that the effect of the destruction of some of these animals for fur is boon for automatic control of the Agriculture crops and other products which otherwise are destroyed by these creatures.

6.7 SELF ASSESSMENT QUESTION

Long Answers Type Questions

1. Describe briefly about Dairy industry?
2. Explain all the processes involved in Fur industry?
3. Describe economic importance of animals to humans with suitable examples?
4. Define breed & explain all the cattle breeds found in India?
5. Write about wool industry & process in it briefly?

Short Answer Type Questions

1. What hormone is important in the milking process?

A. Oxytocin

2. What is Flaying?

Ans. To strip the skin off

3. Name the animals which are reared for fur farming?

Ans. Mink, Chinchilla, Blue fox, Rabbits, Martens, Sheep, Goat etc

4. Name the types of wool found in India?

Ans. Joria, Harnal, Bikaneri, Rajputana, Birbik & Marwar

5. Name well recognised cow breeds in India?

Ans. Sahiwal, Gir, Deoni, Ongole, Kankrej, Rath & Kangayam.

Fill in the blanks:

1. _____ is the major enemy of skin industry.
2. _____ breed of buffalo is the best producer of milk.
3. Musk is obtained from _____, _____ & _____
4. A group of animals related by descent and similar characters like appearance, size and configuration are known as _____
5. The management of animal for milk and its product for human consumption is called _____

Multiple Choice Questions

1. The process of removing the fleece of sheep along with a thin Layer of skin is called :-
 - a. Rearing
 - b. shearing
 - c. Sorting
 - d. Scouring

2. What is the name of process which involves pulling & twisting of strands of a fibre?
 - a. Ginning
 - b. Weaving
 - c. Spinning
 - d. None of these

3. The yellow colour in the creamy layer of milk is caused by
 - a. *Pseudomonas synxantha*
 - b. *Peudomonassyncyanea*
 - c. both a & b
 - d. *S. marcescens*

4. Pashmina is obtained from :-
 - a. Changthangi goat
 - b. Sannen goat
 - c. Jamunapari goat
 - d. Merino goat

5. The highest milk producing country in the world is :-
 - a. U.K.

- b. Germany
- c. U.S.A
- d. India

Answer:

Fill in the blanks:

1. Warble fly
2. Murrah
3. Civet, Musk deer & Skunk
4. Breed
5. Dairying

Multiple Choice Questions:

1. Shearing
2. Spinning
3. *Pseudomonas synxantha*
4. Changthangi goat
5. India

6.8 GLOSSARY

Breeding: the mating and production of offspring by animals

Buffalo: a heavily built wild ox with backward-curving horns, found mainly in the Old World tropics:

Chinchilla: a small South American rodent with soft grey fur and a long bushy tail

Condensed milk: milk that has been thickened by evaporation and sweetened, sold in tins

Dung: the excrement of animals; manure

Dyeing: A process in which the color of a fur is changed

Fur: the short, fine, soft hair of certain animals.

Ivory: a hard creamy-white substance composing the main part of the tusks of an elephant, walrus, or narwhal, often used to make ornaments and other articles

Lagomorphs: a mammal of the order *Lagomorpha*, which comprises the hares, rabbits, and pikas.

Mammals: a warm-blooded vertebrate animal of a class that is distinguished by the possession of hair or fur, females that secrete milk for the nourishment of the young, and the birth of live young

Marten: a semi-arboreal weasel-like mammal found in Eurasia and North America, hunted for its fur

Mink: a small semiaquatic stoat-like carnivore native to North America and Eurasia

Musk: a strong-smelling reddish-brown substance which is secreted by the male musk deer for scent-marking and is an important ingredient in perfumery

Pasteurization: The process of heating milk or cream (and other beverages) to a specific temperature for a specified time to destroy any potential harmful microorganisms and increase its keeping qualities

Phytophagous: feeding on plants.

Ranching: A large farm on which a particular crop or kind of animal is raised

Salting: spraying the powdered salts on the fleshy surface of the skin

Skin: the thin layer of tissue forming the natural outer covering of the body of a person or animal

Tanning: A process in which the raw pelts are skinned, fleshed, soaked, and washed in special solutions to prepare them for use in garments.

7.9 Terminal question & Answer

7.10 Glossary

7.12 References

7.1 OBJECTIVE

1. The objective of this chapter is to understand the pests of stored grain food.
2. To understand their habits & identification.
3. A detailed study of their life-cycles.
4. To understand the nature of damage caused by them.
5. Understanding the precautions & control measures to be taken against them.

7.2 INTRODUCTION

Since the cradle of human race, man has utilised animals for various purposes like food, clothing, weapons etc. If some animals proved to be useful while other caused great damage to the economy of human beings. These not so useful animals are a competition to man for food & natural resources. These are termed as pests, which affect the human beings directly or indirectly. A pest is any animal which becomes a source of nuisance & causes loss to humans. It has been estimated that between one quarter & one third of the world grain crop is lost each year during storage; much of this is due to insect attack. In addition, grain which is not lost is severely reduced in quality by insect damage. Many grain pests preferentially eat out grain embryos, thereby reducing the protein content of food grain & lowering the percentage of seeds which germinate. Direct feeding by stored grain pest reduces grain weight, nutritional value & quality of stored grains. Infestation also causes contamination, odour, mould & heat damage problems which reduces the worth of the grain & result in making it unfit for processing into food for human beings & animals.

SOME COMMON STORED GRAIN PEST'S:-

7.3 PULSE BEETLE (Callosobruchus maculatus)

1. **Pulse beetle (Callosobruchus maculatus):** It is a species of beetle commonly known as cowpea weevil or cowpea reed beetle. It is a member of the leaf beetles family Chrysomelidae hence not a true weevil.

Systematic Position:

Kingdom – Animalia

Phylum - Arthropoda

Class – Insecta

Order – Coleoptera

Family- Chrysomelidae

Genus – *Callisobruchus*

Species – *maculatus*

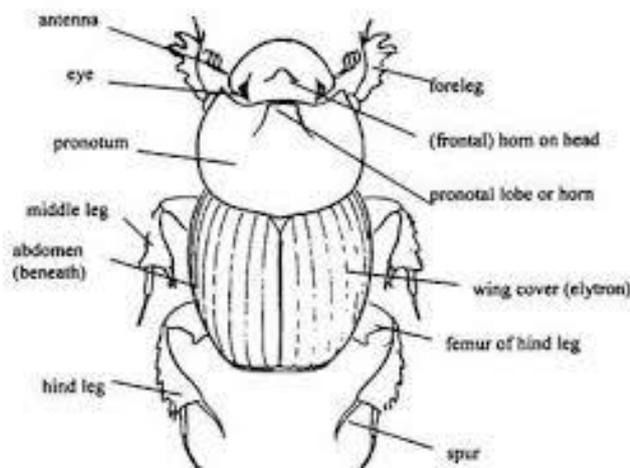

Fig7.1 Pulse beetle

Habits: It is a common pest of stored legumes which is cosmopolitan in distribution except Antarctica. This beetle originated in West Africa & moved around the world with the trade of legumes & other crops. It is a major pest of cowpea, green gram & lentils. It lacks the ‘snout’ of a true weevil; it is elongated in shape, reddish brown in colour with grey & black sheath elytra having two central black spots. The last segment of the abdomen extends out from elytra, which also have black spots. There are two morphological forms of the species i.e. a flightless form & a flying form. The flying form is more common in the beetle that develops in high larval density & high temperature. Flying form has longer life span but lower ability to produce eggs. The beetle is sexually dimorphic as males can be easily distinguished from females as they are brown while females are overall darker. Female beetles are larger than male beetles in size. Elytra are larger in females as compared to males. It is medically harmless to humans.

Life-cycle: A female beetle after copulation lays up to hundred eggs & out of which all hatches. Eggs are layed on the surface of the bean which are small, translucent, shiny, oval, inconspicuous & doomed structures. The duration of egg stage is 5-6 days, upon hatching the larva bite through the base of egg: through the testa of the seed & into the cotyledons. The developing larva feeds entirely within a single seed, excavating a chamber as it grows eating the tissue just under surface leaving a very thin layer through which it exits when get matures. It emerges after a larval period of 3 to 7 weeks depending on conditions as gestation period is shorter in summer while longer in winter. Larval crowding i.e. 9-10 larvae feeding within one bean limits the resources leading to mortality. The larvae takes 24-36 hours to

mature completely into an adult after emerging out, life span of the beetle is 10-14 days. The adult does not require food or water as larval stage is the feeding stage. There are two growth stages namely fruiting stage & post-harvest stage. The adult beetles that emerges out mate with the others that develop on the same host bean.

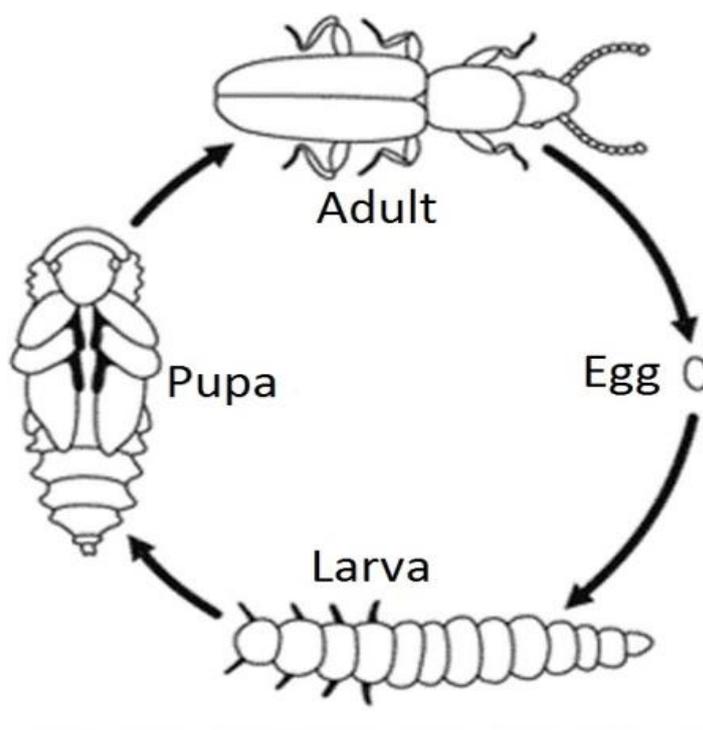

Fig7.2 Life cycle of Pulse beetle

Nature of Damage: *Callosobruchus maculatus* is a serious store pest, causing enormous damage to almost all kind of pulse grains. It prefers cowpea (*Vigna catjang*) but it also infest the seeds of different pulses such as red gram, arhar, lentil, pea, small pea, mung, urid, moth, soyabean, khesari etc. It also causes damage to seeds in pods of red gram in the field. Damage to the pulse grain is mainly caused by the developing larvae. Just after hatching young larvae bores into the grain, feed upon the contents of the grain making them almost hollow and empty, clustering of grains, decay or powdering of pulses which produces foul smell. As development occurs entirely within the seed, the immature stages are not normally seen. The optimum development conditions are 32⁰ C temperature & 90 % relative humidity. As the pods become dry the ability to infest them decreases where as the thrashed seeds are more susceptible to pest attack throughout storage.

Control Measures: For the control & eradication of the beetle following methods should be adopted which are enlisted below.

1. **Chemical Control:** It is the use of chemicals such as fumigants, contact insecticide & pesticides to control storage insects. Chemical measures provide immediate disinfestations of the commodity & the space enclosing it.
2. **Physical & Mechanical Control:**
3. **Biological Control:** Animals used as predators of Pulse beetle are parasitoid wasps (*Dinarmus basalis*) which target small larvae. The organism used as parasite of the beetle is a mite (*Uscana mukerji*) which feeds upon egg & prevents them from hatching.

7.4 RICE WEEVIL (*Sitophilus oryzae*)

Rice-Weevil (*Sitophilus oryzae*): The rice weevil is a stored product pest of not only rice but almost of all cereals & their products. It is called as rice weevil because it's breeding habits & life-cycle was first of all studied in rice

Systematic Position:

Kingdom – Animalia
Phylum - Arthropoda
Class – Insecta
Order – Coleoptera
Family- Curculionidae
Genus – *Sitophilus*
Species – *oryzae*

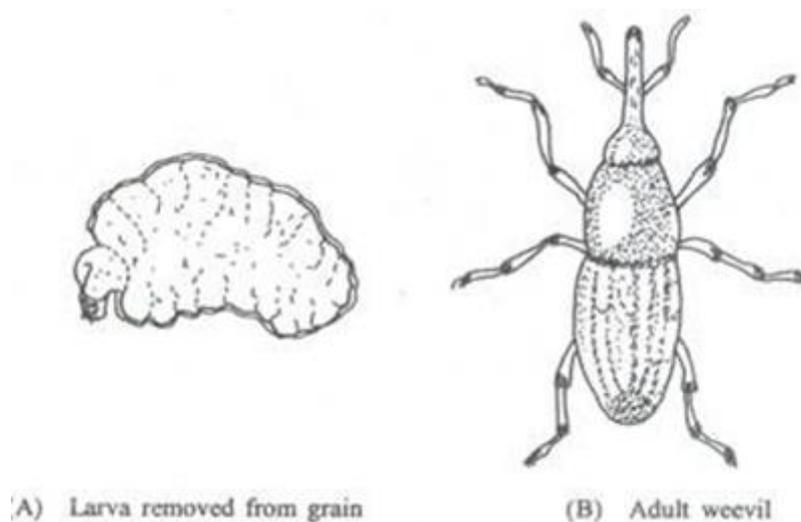

Fig 7.3 *Sitophilus oryzae*

Habits: It is the commonest pest that one encounters in all kinds of stores. It is believed that it originated in temperate countries. But now days it is the most widely distributed stored product pest of the world through shipments of rice. It commonly occurs in temperate &

warm countries, rice weevil does not only attacks rice but several crops like wheat, maize, barley etc. Rice weevil causes the most substantial loss to stored grains in world amounting 18.30%. The beetle has a relatively short developmental period & high populations can easily be built up, adult weevil is reddish brown in colour measuring 3-4 mm in length. Head is projected forward into a long snout like rostrum with a pair of stout mandibular jaws at the extremity of the rostrum. Four light red spots on elytra are arranged in a cross on the wing covers due to this it is easily confused with the similar looking maize weevil. Females are larger than males & sexual dimorphism occurs as rostrum of males is shorter, broader as compared to the females. Adult weevils are able to fly.

Life-cycle: After copulation, adult female bores a hole in the grain with the help of its powerful jaws & deposit a single egg in the grain cavity. In search of suitable site in the grain a mother beetle may bore at several parts of a grain but only one egg is laid down in a single grain, female can lay up to 300-550 eggs in 4-5 months i.e. 2-6 eggs per day. Eggs are deposited within the hole sealing it with the gelatinous fluid secreted from her ovipositor, which are white, elastic, tiny & oval in structure. The egg hatches within 4-5 days under optimum conditions, the larva develops within the grain hollowing it out while feeding leaving the shell intact. The tiny, white, fleshy legless grubs with yellowish brown head & biting jaws bores down into the grain, feeding on its starchy content. The grub stage lasts for 19-34 days & a fully matured grub makes a pupal cell inside the grain called as eclosion & pupates. The pupal stage lasts for 3-6 days under optimum conditions but in unfavourable conditions it may extend up to 20 days. The adults formed after pupation bores its way out of the grains, immediately after emergence the adult weevil are ready for breeding. The duration of life cycle of rice-weevil & number of generations completed in a year depends upon the weather conditions like temperature & humidity; 5-7 generations are completed in a year. The size of the newly bored adult weevil is directly proportional to the size of the grain in which the

larval period has been spent, larger & healthier grains produces larger & healthier weevils.

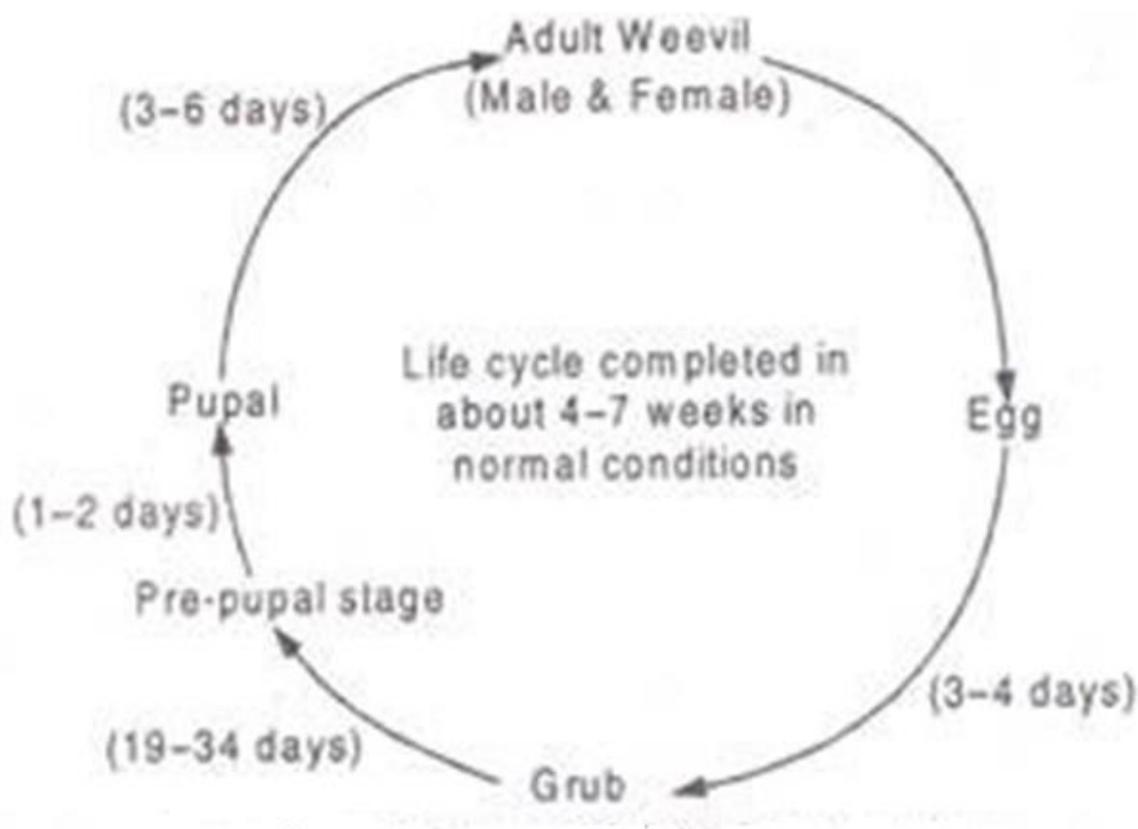

Fig 7.4 Life cycle of the *Sitophilus oryzae*

Nature of Damage: As adult rice weevil can fly, they fly down to nearby fields where it infests the ripe grains, both adults & larva feed upon the grains making them inconsumable. The damage caused by them extent up to 50% of the total grain stored at a particular place. Larvae are the more destructive as they feed voraciously on the content of the grain but leave the shell of the grain intact. Adults also feed upon flour i.e. milled cereals but the larvae cannot develop in it unless the material is caked. Feeding causes clustering of grains producing foul smell.

Control-Measures: For the control of rice weevil following methods should be adopted-

- 1. Physical & Mechanical Control:** The weevil is unable to breed at a grain moisture content of 9%, hence dry storage of grains can avoid infestation by the pest. Previously infested grain & its debris should be removed out from trucks beds, transport wagons, grain dumps & elevator buckets to avoid re-infestation during new storage. Ceilings, walls, ledger, braces & handling equipments should be thoroughly cleaned or removed which are ideal places of hiding. Thermal disinfestation techniques should be implanted by drying grains on a

concrete platform by the increasing the temperature up to 60°C for 10 minutes. Mechanical disinfestation includes refinement of grains from simple turning of grains through bulk handling systems to the use of sophisticated percussion machines in flour mills etc.

2. Chemical Methods: This method includes use of various chemical techniques like fumigation, insecticide, aerosol sprays, traps etc to eradicate rice weevil.

(i) Fumigation: It is the use of toxic gas to disinfest a commodity in an enclosure, the purpose of fumigation is to obtain immediate relief from pest. Phosphine is mainly used for fumigation against rice weevil.

(ii) Insecticides: These chemicals are used as surface layering for eradication of insects; these are available as dust formulations admixed with cereals or as liquid treatments.

E.g. Malathion, Lindane, Permethrin etc

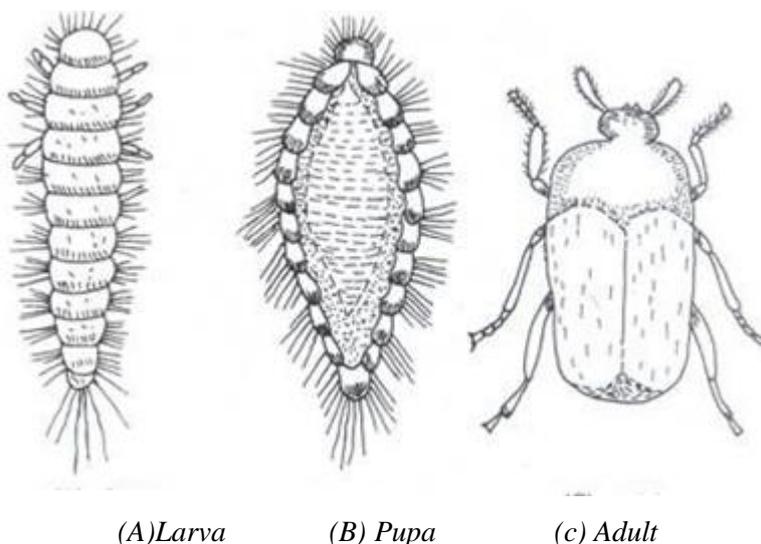

(iii) Aerosol Spray: After vacuuming of the storage areas, it is disinfested by spraying FS MP Aerosol which is odourless & fast acting. It can be used in those areas which are left unaffected by other means such as sink, pantries, cabinets, cervices, cracks etc where adults & larvae of the pest likes to hide. Another spray used is PT-PHANTOM.

(iii) Rice-weevil Traps: These traps acts on the pheromone, it is placed where weevil suspect activity is observed. This trap uses strong pheromones or attractants to lure adults, once they crawl or fly into the holding tray, the thick catching oil will hold them.

(2) Biological Control: The organism used for the predation of rice weevil is parasitoids *Anisopteromalus calandrea* which attacks the larvae & adults & stop their development.

7.5 WHEAT WEEVIL (Trogoderma granarium)

Wheat Weevil (*Trogoderma granarium*): The pest is cosmopolitan in distribution; it is also called as cabinet beetle. It initially originated in South Asia, wheat weevil is regarded as the most destructive pest of the grain products & seeds.

Systematic Position:**Kingdom** – Animalia**Phylum** - Arthropoda**Class** – Insecta**Order** – Coleoptera**Family** – Dermestidae**Genus** - *Trogoderma***Species** – *granarium*

(A) Larva (B) Pupa (c) Adult
 Fig 7.5 *Trogoderma granarium*

Habits: *Trogoderma granarium* is considered as the worst invasive species worldwide, it is a major pest of wheat in the Indian subcontinent, U.S.A, U.K & Germany. It is more commonly found in the warmer & dry regions with low moisture content food, beside wheat it also infest barley, oats, rye, maize, rice, flour, malt & noodles also. It is omnivorous in nature as it feeds upon dried blood, dried milk, fish meal, wool, goat skins, dead mice & dried insects. The adults are characterized by oblong-oval, light to dark brown coloured body bearing markings; body is covered with fine hairs which give a velvety appearance. Elytra contains indistinct red brown markings, rostrum is well developed especially in males. Eyes are emarginated; head is small & usually deflected with 11 segmented antennae. Males are smaller than females, adult weevil have wings but usually don't fly & feed very little. Adults are short lived as life span of males is 7-12 days where as that of females is 20-30 days but mated females live up to 4-7 days only.

Life-Cycle: After 2-3 days of emergence, copulation takes place between adult beetles, the Female start laying eggs after 5 days of mating. The eggs are generally laid in crevices in godown or in grain heaps, average number of eggs laid by a single female per day is 25 which last for 5-7 days. The eggs are laid 40°C which are initially milky white, later pale yellowish, typically cylindrical with one end rounded & the other more pointed bearing a number of spines like projections, broader at the base & tapering distally. Eggs are laid loosely & singly in the host material, which hatch in 8-14 days at optimum conditions. There are five moults in the development of larvae & cast skin is shed following each moult, larval duration lasts for 30-50 days. During unfavourable conditions the number of moults increase

up to 8-10 level & the larval duration prolong for a period of 200 days to 4 years. In winters or in scarcity of food the larvae enter diapause & development ceases, it remains inactive & lives in crevices, cracks or other concealed places. Young larvae are unable to feed upon whole grains & depend on damaged grains. Larvae are uniformly yellowish white, except head & body hairs are brown, as the larvae increases in size their body colour changes to a golden or reddish brown & more body hairs develop. Head is barbed with segment like constrictions & tail is shorter. At the last ecdysis i.e. moulting of cuticle, the larval skin splits but the pupa remains within the skin for the whole of its life. After 6-16 days of pupal period adult weevils emerge out which become sexually mature immediately. The development takes 4-6 weeks for completion at 95⁰F optimal temperature.

Nature of Damage: It is considered to be a serious pest of stored wheat grains along with it also attacks rice, maize, oat, jaw pulses, oilseeds & other products like copra, dry fruits etc. The damage to the grains is caused by the larval stages while the adults are harmless as they do not feed. This pest is mostly active during July-October period in which they are capable of causing heaviest damage to stored grains. The infestation occurs mainly at superficial layers of grain as the pest is not able to penetrate deep into the grain. The destruction of the embryo of the grain is the major damage caused by this pest but during heavy infestations complete grain is damaged. Reproduction of the beetle is so rapid that larvae are found in large numbers on the surface of grain, they spread generally by movement of infested goods & container during diapause condition. The most favourable conditions for multiplication & damage is in bulk grain under extended storage, apart from the destruction of grain products by beetle, infested products contaminated with body parts, setae & cast larval skins result in gastro-intestinal irritation, asthmatics & allergens to sensitised individuals.

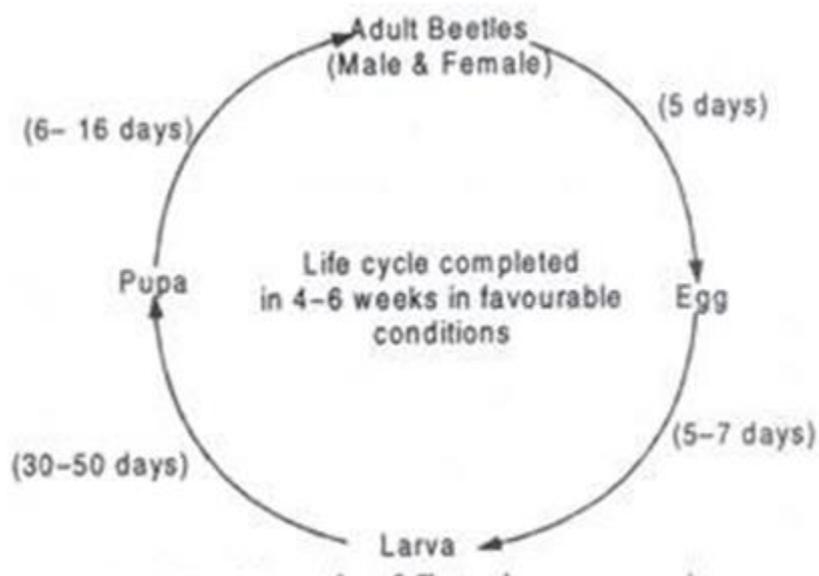

Fig 7.6 Life cycle of the *Trogoderma granarium*

Control-Measures: The obvious signs of kharpa beetle infestations are the larvae & cast skins, for its eradication following control measures should be adopted-

1. Chemical Control: This method includes use of various chemicals means such as fumigation, insecticide, irradiation, spray etc to eliminate the pest.

(i) Fumigation: The fumigants which are used to control kharpa beetle work at higher dosage as this beetle is resistant to fumigants which are generally used for other stored grain pests. High concentration of fumigants is to be maintained over the fumigation period to allow penetration into all cracks & crevices. The most effective fumigant is the Methyl Bromide which is used in enclosed conditions, other fumigants used is Phosphine at 10⁰C which helps in destroying of pest & its larvae.

(ii) Irradiation: Irradiation is the use of ultra-violet rays to sterilise the adult beetles & disrupt their life cycle, which keep a check at the population of weevil.

(iii) Neem powder: It is an effective & cheap method to control the pest in stored conditions where it repels the kharpa beetle due to its strong odor & also antipest ability.

2. Physical & Mechanical control: This type of control methods includes disinfestation of the commodity by heating, using trapping nets, cleaning of grains by machines etc.

(i) Heating: This step involves drying of wheat grains prior to storage by solar heat on a cemented surface or metal sheets, the grain temperature is increased up to 60⁰C & maintained for 10-20 minutes, which kills the live pests of grains i.e. larvae & adult weevils.

(ii) **Trapping nets:** These are used in warehouses & other storage facilities; it combines a feeding attractant for larvae while a pheromone for adult males. The method is based on using sticky traps placed on a suspended position; these specialised traps used for the species *granarium* are wall mountable, known as the Biolure box trap.

3. **Biological Control:** Biological control is an efficient & healthier alternative method of chemical use in eradication of pests, the predator used to control the kharpa beetle is a parasitoid *Laelius padatus* (wasp) which stings the developing larvae & releases its egg inside the body. The developing wasp inside pest larvae feeds upon it & emerges out when it is dead.

7.6 RUST RED FLOUR BEETLE (*Tribolium castaneum*)

Rust red flour beetle (*Tribolium castaneum*): The weevil is commonly called as rust red flour beetle, it is cosmopolitan in nature. It initially originated in the Indian Subcontinent but now found throughout all tropical, subtropical & warm temperate regions of the world.

Systematic Position:

Kingdom – Animalia
Phylum - Arthropoda
Class – Insecta
Order – Coleoptera
Family – Tenebrionidae
Genus - *Tribolium*
Species – *castaneum*

Table 1. The mean developmental time in days for *T. confusum* at 29°C.

<u>Life stage</u>	<u><i>T. confusum</i></u>
egg	5.5
larvae	22.4
pupae	7.0
Total	34.9

Fig 7.7 *Tribolium castaneum*

Habits: It is a worldwide serious pest of stored products particularly food grains like flour, cereals, pasta, biscuits, nuts, oil cakes, dried fruits, meal beans, dried pet food, dried flowers, chocolate seeds & even dried museum specimens. This beetle is the most important pest of stored products inside the home, food industry & grocery stores. It is different from the confused floor beetle (*Tribolium confusum*) by having different antennae shape & its ability to fly under stressed conditions. The body of the adult beetle is flattened reddish brown in colour, thorax & abdomen are distinct. Antennae are well developed, eyes are reddish black in colour, chewing mouth parts present & grooved wing covers with last few segments being abruptly much larger. Female beetles are polyandrous in mating behaviour i.e. during a single copulation period; a single female will mate with multiple different males. This polyandrous mating behaviour by female beetles is shown in order to increase their fertility assurance, by mating with an increased number of males, female beetles obtain greater amount of sperm. The adults are long lived as females can live up to 3-4 years.

Life-Cycle: After copulation a female beetle lays about 400-500 eggs, which are laid singly in flour & dust of the grains, they soon get covered with small particles of dust & flour as they are moist & sticky when freshly laid. Eggs are minute, slender & cylindrical in shape with rounded at both ends & of whitish colour, they hatch in 5-12 days under favourable conditions. The freshly hatched grub is small, worm like, cylindrical & wiry in appearance, body segments have a number of fine hairs and the terminal segment is furnished with a pair of spine like appendages. The grub is pale yellowish in colour, larvae go through 5-12 instars and the larval period ranges from 27-29 days under favourable conditions. Pupation takes place on the surface of food; pupa is naked in appearance, initially white but gradually becomes yellowish, pupal stage lasts for 5-7 days. The total life cycle from egg to emergence of adult takes about 6 weeks, there are about 4-7 generations in one year.

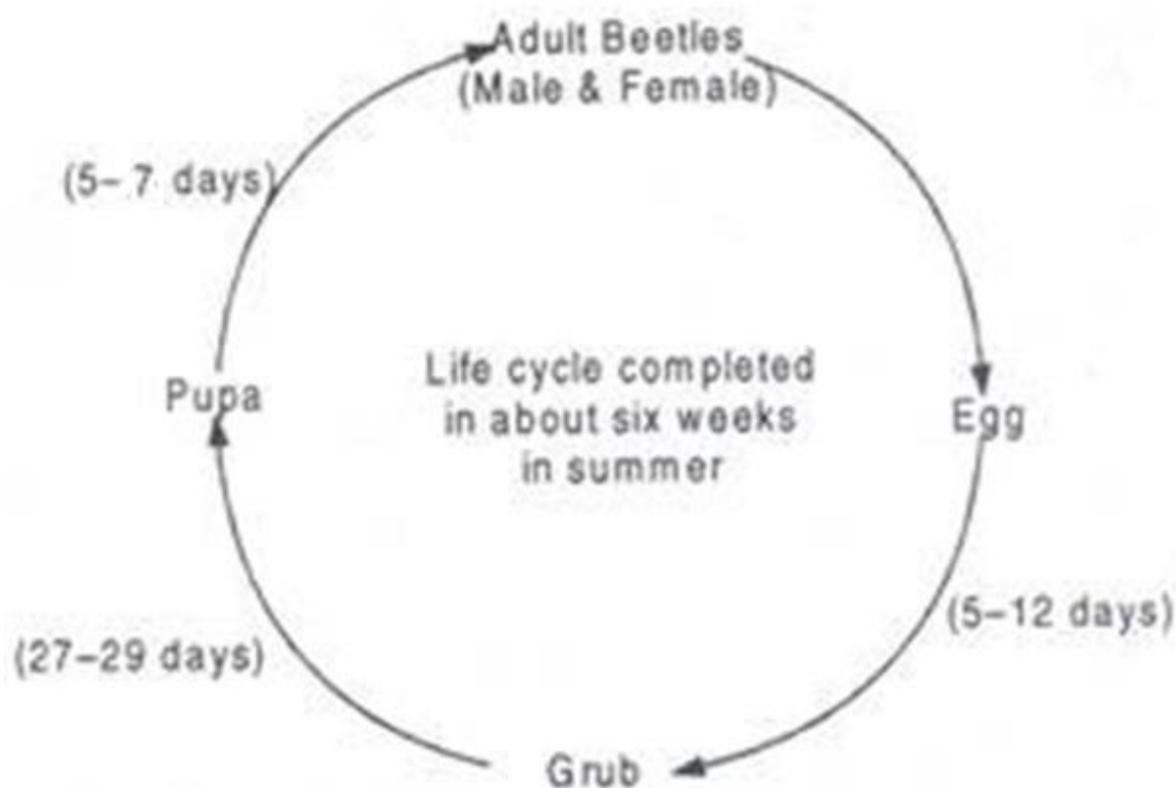

Fig 7.8 Life cycle of the *Tribolium castaneum*

Nature of Damage: This pest is found infecting all stored products, both the larvae & adult cannot damage sound grains, but they feed on those grains which already have been damaged by other pests. The main strength of rust red flour beetle is its high reproductive rate, quick maturing to adult stage with easy dispersal & migration which leads to a new colony with help of few individuals. It is a serious pest of prepared cereal products such as atta, suji & maida found in abundance in flour mills, in case of heavy infestations flour & maida turns greyish-yellow & develop red taints which become mouldy & emits pungent foul smell. It also damages the seeds & grain by feeding internally, contaminating with its larval casts & faeces.

Control Measures: *Tribolium castaneum* can be controlled by the implantation of the following measures which are as follows –

1. **Chemical measures:** Applications of chemicals sometimes become essential for complete mortality & prevention of the weevil.

(i) **Fumigation:** It is a procedure by which stored grain pests are removed by means of poisonous gas called as fumigant. The fumigant is produced & concentrated as a gas is lethal for the specific living pests, the gas penetrates into the interior of largely invisible, incipient

eggs & larvae. Generally Methyl bromide, Magnesium & Aluminium phosphide are used as fumigants.

(ii) **Insecticides:** These are used as surface treatments by making a cover or layer above the infested commodity with the pests. These insecticides come in various forms like powder & liquid. Examples are Tetrachlorovinphus, Melathion, Deltamethrin, Diazinon etc.

2. **Physical & Mechanical methods:** It involves following methos-

(i) **Reducing intergranular space:** As adult beetles being very soft & weak at the beginning cannot move freely in grains & are restricted to top layer hence to stop their movement deep into the grain mass is done by placing 7-10 cm layer of dry sand at the top of grains. To prevent mixing of sand with the food, a paper or polythene sheet is placed on the top surface of commodity.

(ii) **Coating with Oil:** This technique is only for the small quantity of grains in which non-drying oils is mixed uniformly with whole grains are kept in closed container. The layer of oil prevents laying of eggs or larvae hatching on grain surface. The oils preferred for this purpose are Neem oil, Vegetable oil, Castor oil, Niger oil, Sesame oil etc.

(iii) **Drying heating:** In this method solar drying of infested grain is done on a cemented platform & the temperature is raised upto 60⁰C & maintained for 20 minutes, which kills the pests if any present. Solar absorbance surfaces are best used for this technique.

3. **Biological control:** The rust red flour beetle can be controlled by parasites, parasitoids & predators that affect its different stages of life cycle.

(i) **Entomopathogens:** A fungus *Brauveria baesiana* is used as an entomopathogen of the beetle which causes white muscardine disease, leading to formation of microscopic spores which when come in contact with the body of pest germinates, penetrates cuticle & grow inside killing the pest within few days. It is an epidemic disease which travels from one individual to another leading to massacre of beetles.

(ii) **Parasites:** The mite *Acarophenax lacunatus* which is parasitic in nature is used to feed upon the larvae of the beetle & stops its growth.

7.7 LESSER GRAIN BORER (*Rhizopertha dominica*)

Lesser Grain Borer (*Rhizopertha dominica*)

It is commonly called as lesser grain borer & Australian wheat weevil, it is considered as second destroyer of stored grains after rice weevil. It initially originated in the Indian subcontinent, but now is cosmopolitan in distribution.

Systematic Position:

Kingdom – Animalia

Phylum - Arthropoda

Class – Insecta

Order – Coleoptera

Family – Bostrichidae

Genus - *Rhizopertha*

Species – *dominica*

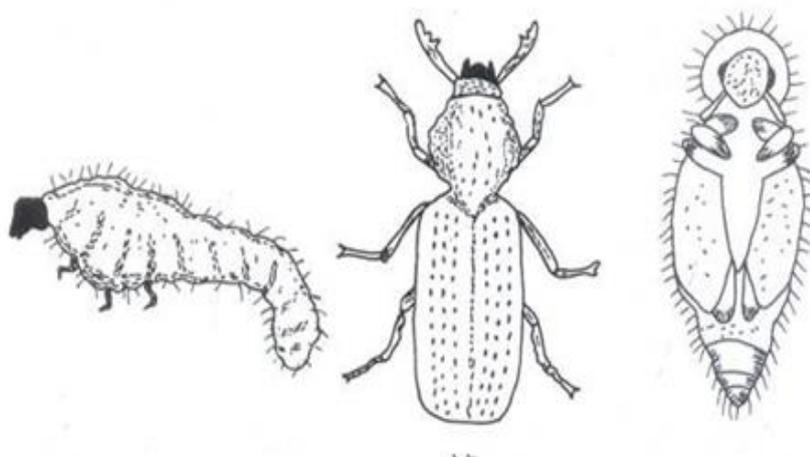

Fig 7.9 *Rhizopertha dominica*

Habits: It is the serious pest of stored products throughout the tropics, Australia & USA. It is also found in temperate countries due to its ability for prolonged flight & international trade of food products. It is found mainly in cereal & food stores also in animal feed processing facilities, it largely feeds on stored cereal seed including wheat, maize, rice, oats, barley, sorghum & millets beside these it is also found on a wide variety of foodstuffs including beans, dried chillies, turmeric, coriander, ginger, carrava chips, biscuits & wheat flour. It can be distinguished from other store pests by its cylindrical shape & small size, it measures about 3mm in length. Adult beetle is polished dark brown or black in colour with a roughened surface. Head is inserted into a hood-like triangular structure lying under the thorax; head possesses powerful jaws with which it causes serious damage to grain & also any part of the wooden structure in the store to hide over unfavourable conditions. The elytra are parallel sided; head is not visible from above with propotum having rasp like teet at front.

Life-Cycle: After copulation the mother beetle lays 300-500 eggs singly or in clusters near the embryo end of the grains, eggs can also be simply dropped down between grains & are also laid in powdery starchy materials lying outside. Eggs are pear shaped; glistening white when freshly laid, but become pinkish opaque as the larvae start developing inside the egg shell. The duration of egg stage is 5-6 days during summer, while 7-11 days during winter, the newly hatched larva is quite active & is campo-deiform in shape i.e. C shaped grub creamy white in colour. It burrows at once into the grain or crawls' actively feeding on the loose starchy material; grub completes its development either within grains or in the flour where it undergoes larval mounds. There are three larval instars; the first two instars are not recurved while the third & fourth instars have head & thorax recurved towards abdomen. A fully grown larva is dirty white in colour with brown head, which is retracted into thorax, three pairs of legs with swollen anterior end. The whole body is covered with tiny hairs, average larval period is about 40 days, pre-pupal & pupal period's lasts for a week & it changes into adult form. The adults eat their way out of the grain, which are winged & may fly, the total life cycle from egg up to emergence of the adult is about 6-8 weeks. There are generally 5 generations in a years, adults live for 4-8 months, life cycle may be completed outside the grain as it is found breeding on flour.

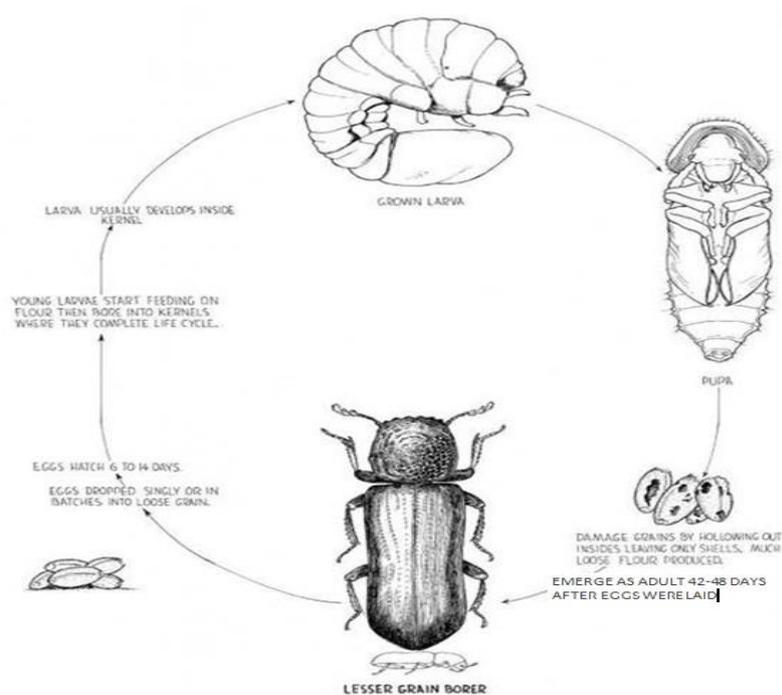

Fig 7.10 Life cycle of the *Rhizopertha dominica*

Nature of Damage: Both the larvae & adults are destructive in nature i.e. primary pests; it bore irregularly shaped holes into whole grains causing weight loss of grains. It reduces rice to dust & also produces more faeces i.e. excreta than any other species, it can tolerate the moisture content as low as 7 percent. Grains when heavily attacked by this pest are hallowed out, until a thin shell remains, the larger grains such as maize up to 4 beetles can be found at a time in a single grain. If the female lays eggs away from grains only the first stage larvae are able to enter the grain because of their straight body while the second stage larva due to its curved shape cannot penetrate the grain. It causes weight loss of grain up to 40% besides any other species of stored grain pest, it also reduces germination rates & vigour of the grains letting it easy prey for secondary pests & fungi. The larvae of beetle emerging out from eggs laid near the grain straight way enters into the grain.

Control-Measures: Prevention is always the most economic & efficient method of controlling these pests, following methods can be adopted to eradicate the pest.

1. Chemical control

(i) **Fumigation:** Once the pest is distributed within the grain mass, fumigation is the only method of relieving the problem. Phosphine is the commonly used fumigant to control insect infestations in stored conditions; other fumigants used are Magnesium phosphide, phosphine mixed with CO₂.

(ii) **Insecticides:** These are generally sprayed on surface as they degrade faster, the period of protection depends upon commodity treated temperature, grain moisture content & insecticide used. These remove pests populations from buildings, store house & godowns. The commonly used insecticides for eradication of the weevil are Wheat-ENT47, Soyabean-ENT13, Corn-ENT16, Neonicotinoids, Methoprene & diflubenzuron etc.

(iii) **Insect growth regulators (IGR):** These are sprayed or dusted directly onto the grain & protect grain from infestation from two weeks to one year. It controls the adults by suppressing progeny production & also causes mortality, these IGR have low toxicity to mammals but takes longer to control the pest & are more expensive than other insecticides, fumigants & chemicals. Commonly used IGR are Methoprene, Pyriproxyfen, Lufenuron & Fenoxycarb.

2. **Biological control:** By the use of natural enemies like predators, parasites, parasitoids & entomopathogens.

(i) **Predators:** *Ferretiosoma nigrescans* i.e. clown beetle is able to feed on the larvae. *Xylocoris flavipes* i.e. reutes feeds upon the instar larval stages of the pest.

Cheyletus eruditus known as hunting mite feeds upon eggs of the beetle.

(ii) **Parasites & Parasitoids:** Parasitic egg mite *Acaroph enax lacunatus* is used as a parasite of the beetle. Generally hymenoptera parasitoid used against the beetle are *Anisopteromalus calandrea* & *Choetospila elegans* are effective in reducing beetle as they are very small, do not feed on grain & can be easily removed from grains as it attacks the larva of beetle that are feeding inside the grain.

(iii) **Entomopathogens:** These are bacteria, fungi, protozoans or viruses which act as endoparasite of insects that enters into host through natural body openings & causes virulence. The commonly used entomopathogens for the beetle are Bacteria(*Bacillus thuringiensis*), Nematode(*Steinernema felitae* & *Steinernema carpocapsae*), Fungi(*Beauveria bassiana* & *Metarhizium anisopilae*).

3. **Physical & Mechanical control:** The measures to control insect infestation generally used are cleaning & drying, mechanical disinfestations includes refinement of the grain through simple handling system to the use of sophisticated machines like entoleters etc. Physical control includes thermal disinfestations by heating of grains through simple exposure to the heat of sun. In this traditional procedure disinfestation is achieved by exposing grain in thin layers to the sun light on a cemented platform that will drive off any adult or larvae. Hot air grain drying systems are also used for this purpose in the reconditioning of infested grain.

7.8 SUMMARY

Insects are of great importance to the mankind from centuries, some are beneficial while others are harmful in different ways. Insects cover more than $\frac{3}{4}$ of the entire world fauna, insects attack a large number of crops in the field & causes great loss to human health & economy. Of all demands of man, food is the prime importance & because of population pressures the task of increased food production has become all the more important. Human struggle against pests of stored grains is very old, as it loses one third of the food produced to pests around the globe. The numbers of known insect species causing damage to crops are about 1000 out of which 70 species are responsible for maximum loss.

Most of the pests of store grains belong to order Coleoptera which contains mostly Weevils & beetles. The word "coleoptera" is from the Greek, *koleos*, meaning "sheath"; and, *pteron*, meaning "wing", thus "sheathed wing", because most beetles & weevils have two pairs of wings, the front pair, the "elytra", being hardened and thickened into a shell-like protection

for the rear pair and the beetle's abdomen. The order contains more species than any other order, constituting almost 25% of all known animal life-forms. The diversity of beetles & weevils is very wide-ranging. They are found in almost all types of habitats. The major insects damaging food products are Pulse beetle, Rice weevil, Wheat weevil, Rust red flour beetle and lesser grain borer.

Pulse beetle (*Callosobruchus maculatus*) is a serious pest of stored gram & cowpea, grub is the infective stage for stored food grains. The holes on grains are the first evidence of infestation; infested grains become useless for human consumption. Rice weevil (*Sitophilus oryzae*) is the most common & widely spread stored food pest around the globe, its larva are more destructive causing damage up to 50%. It not only attacks rice but many other cereals & food grains.

Wheat weevil (*Trogoderma granarium*) is also called as cabinet beetle, the worst invasive species worldwide. There are five moults, omnivorous in nature, rapid reproduction causing heavy infestations to the food grains. Rust red flour beetle (*Tribolium castaneum*) is called as rust red flour beetle, cosmopolitan & polyandrous mating nature. A serious pest of prepared cereal products, infecting internally & producing foul smell in food products, flies under stressed conditions.

Lesser grain borer (*Rhizopertha dominica*) it is the Australian wheat weevil, possess ability for prolonged flight. 5 generations in a year, both the larvae & adults are destructive as causing weight loss of grains. It reduces rice to dust & produces fraes in larger amounts. Control measures of food grain pests are necessary as they causes heavy economic loss, which includes chemical, mechanical, physical & biological.

Chemical control produces immediate effect as it removes heavy infestations by the help of fumigation, insecticides, insect growth regulators & aerosol sprays but they are harmful to humans also as produces delitrous effects when chemically treated food grain consumed. Physical method involves thermal drying & mechanical method includes cleaning, drying, refinement & use of sophisticated machines. Biological control is the safest method for pest control as it has no side effects upon human health; it uses natural enemies like parasites, predators, parasitiods, entomopathogens & hormonal traps.

7.9 TERMINAL QUESTION & ANSWER

Self assessment Questions

Long answer type questions

1. Describe the habit and life cycle of Pulse beetle in detail?
2. Explain the nature of damage caused and control measures of Rice weevil?
3. Explain the life cycle of Wheat weevil with help of diagrams?
4. What are the control measures of store grain pests explain in detail?

Short answer type questions

1. **Name some storage pests belonging to Tenebrionidae?**

Ans. Red flour beetle & Long headed flour beetle.

2. **Name a dermestid storage pest?**

Ans. Khapra beetle is a dermestid storage pest.

3. **Name the pests that occur both in the field and storage?**

Ans. Rice weevil & pulse beetle are the pests that occur both in field & storage.

4. **Pulse beetle prefers which type of pulse?**

Ans. Pulse beetle prefers split pulses.

Fill in the blanks

1. Presence of irregular holes of 1.5 mm diameter on grains of rice, sorghum, wheat, barley, maize in storage is due to attack by _____
2. Merely placing the gunny bags on the heap of grains helps in the collection of _____
3. Adults of _____ are powerful fliers and can move across godowns
4. Long headed flour beetle: *Latheticus oryzae* resembles _____

5. Gaseous quinones released to the medium produces a readily identifiable acid odour in heavy infestations of _____

Multiple choice questions

1. Adult beetles infesting stored products are characterized by:
a. rather hard shell-like bodies **b.** soft, very fragile bodies **c.** transparent body walls **d.** body covered with scales and hairs
2. In general, stored grain mass temperatures above allow insects to survive in lower moisture content:
a. 30°F **b.** 40°F **c.** 50°F **d.** 60°F
3. The stored grain infesting weevil does not fly.
a. Maize weevil **b.** Granary weevil **c.** Rice weevil **d.** Lesser grain weevil
4. Pheromone and food attractant traps may include:
a. Perforated plastic probes **b.** Multi-layered corrugated paper **c.** Wing, delta, and diamond traps **d.** All the above
5. To be effective fumigants must:
a. Be applied in enclosed areas **b.** Reach a lethal concentration in all areas **c.** Be held at a lethal concentration for a minimum amount of time **d.** All the above
6. The pheromones used in warehouse storage of processed commodities attract both sexes of the species:
a. Repelling **b.** Sex **c.** Aggregation **d.** Reproduction

Answers

Fill in the blank:

1. Rice weevil: *Sitophilus oryzae*
2. Khapra beetle: *Trogoderma granarium*
3. Lesser grain borer: *Rhizopertha dominica*
4. Tribolium castaneum
5. Red flour beetle: *Tribolium castaneum*

Multiple choice questions

1. a
2. d
3. b
4. d
5. d
6. c

7.10 GLOSSARY

Antennae:paired sensory organs originating on the insect head

Apex:the portion of a body part farthest from the base or point of attachment. The apex of the elytra is the portion at the rear end of the elytra.

Bacillus thuringensis: A bacteria used as biopesticide.

Coleoptera:*the order comprised of the beetles; sheath winged*

Cowpea: A food-legume crop belonging to the Vigna family, resistant to dry climate conditions.

Diapause:a condition of suspended animation; no activity or development occurs

Elytra:first pair of wings that are modified to form a hard shell

Flour beetle: A pest which feeds with grains and flour, resistant to pesticides

Grain borer: A cosmopolitan beetle living in and that eats stored grain

Grub: an insect larva in the Order Coleoptera

Head:the first or anterior division of the insect body where the eyes and antennae are found

Integument: outer covering or cuticle of the insect body

Instar: The growth period between molts. (The term is usually applied to arthropods.)

Khapra beetle: Pest of stored grains

Larval: pertaining to immature stage of juvenile insects

Mandibles: first pair of jaws in insects

Oil cake: Small residues of oil seeds after oil extraction, used as fodder

Organochlorine insecticide: A kind of insecticide which is not easily cleared, as it is passed along the whole alimentary chain, and has a strong impact on the environment

Snout: lengthening of the head to give the appearance of a nose or snout

Ventral: The under surface of the abdomen; from below

Weevils: Any beetle from the Curculionoidea superfamily. Weevils are less than 6mm (0.24in), and herbivorous

8.1 OBJECTIVE

- The objective of this chapter is to keep the pest number below ETL (economic threshold level) instead of their eradication.
- To understand the various types of pesticides.
- To understand the conservation of environment including bio-diversity.
- To understand how crop protection be made feasible, safe & economical.
- Understanding various preventive measures & their health effects.

8.2 INTRODUCTION

Integrated pest management (IPM), also known as **integrated pest control (IPC)** is a broad-based approach that integrates practices for economic control of pests.

The concept of Integrated Pest Management is nothing new and is widely implemented on field crops and orchards throughout the world. Implementation in the urban environment, in home gardens, landscapes, golf courses and structural settings, presents special challenges. Urban IPM or pest control programs that incorporate reduced use of pesticides in homes, private and commercial landscapes, golf courses and structural settings, is an expanding field with increased support from university and industry research.

After World War II, the research scientist and chemical industries started to produce pesticides of various types. Plant protection measures have included legal, physical, mechanical, cultural, biological, chemical etc. singly or in combination, though with different degree of success. The physical measures involve mainly cold storage and exposure to dry or steam heat. Irradiation of grains and use of electric shocks are yet on a pilot scale. Mechanical measures are used locally for specific cases. The cultural methods of clean cultivation, destruction of infested plants and crop rotation etc. are widely adopted biological control measures has been successful in case of some insect pests but chemosterilization has not yet made any major impact in the field of plant protection.

Introduction to IPM

IPM is based on taking preventive measures, monitoring the crop or site for the level of the pest(s), assessing the potential for pest damage, and choosing appropriate actions. Many different tactics may be available, including cultural practices, biological control agents, pesticides, pest-resistant varieties, mechanical methods and physical barriers. In IPM, these tactics may be combined into a plan that best suits the particular situation. It is a comprehensive approach dedicated to removing causes rather than just treating symptoms.

Almost all farmers do at least some IPM through normal crop production practices. Integrated pest management is a balanced, tactical approach to pest control. It involves taking action to anticipate pest outbreaks and to prevent potential damage. IPM utilizes a wide range of pest control strategies or tactics. The goal of this strategy is to prevent pests from reaching economically or aesthetically damaging levels with the least risk to the environment.

IPM programs are very site-specific. IPM is based on the identification of pests, accurate measurement of pest populations, assessment of damage levels, and knowledge of available pest management strategies or tactics that enable the specialist to make intelligent decisions about control. IPM offers the possibility of improving the effectiveness of pest control programs while reducing some of the negative effects. Many successful IPM programs have reduced pesticide use and increased protection of the environment.

Pesticide use is and will continue to be significant in food and fiber production, forestry, turf and landscape maintenance, and public health. Pest management has shifted from relying

heavily on pesticides to using an integrated approach based on pest assessment, decision making, and evaluation.

Defining IPM

Since the 1930's, over 60 definitions of IPM have been published. Here is a basic definition which will be used.

Integrated Pest Management (IPM) is the coordinated use of pest and environmental information along with available pest control methods, including cultural, biological, genetic and chemical methods, to prevent unacceptable levels of pest damage by the most economical means and with the least possible hazard to people, property, and the environment".

Integrated means that all feasible types of control strategies are considered and combined as appropriate to solve a pest problem.

Pests are unwanted organisms that are a nuisance to man or domestic animals, and can cause injury to humans, animals, plants, and property. Pests reduce yield and/or quality in plants ranging from field crops, fruits and vegetables, to lawns, trees, and golf courses.

Management is the process of making decisions in a systematic way to keep pests from reaching intolerable levels. Small populations of pests can often be tolerated; total eradication is often not necessary, or feasible.

The Basics of IPM

All of the components of an IPM approach can be grouped into three activities. The first is **monitoring**; the second is **assessing the pest situation**; and the third is **taking action**.

- (i) **Monitoring:** Supervising activities in progress to ensure that they are on course and on schedule, in meeting the objectives and performance target.
- (ii) **Assessing the pest's situation:** It is a frame work of macro environmental factors used in the environmental scanning component of strategic management.
- (iii) **Taking action:** Researches on attractants, repellants, pheromones, chemosterilants, hormones, insect pathology, insect nutrition, host resistance and biological control has great importance. For success through integrated pest management a well balanced training programmes with high competence, dedication with cooperativeness is essential among the entomologist of the field.

IPM is information intensive and relies on scouting and monitoring programs for the collection of field data about key factors such as:

- Pest population identification
- Disease pressure
- Weather conditions and degree-days
- Pest date of first occurrence of biological events in their annual cycle
- Crop growth stage
- Presence, reliance and preservation of beneficial organisms

IPM uses decision support systems for determining if control measures are necessary and what measures are most appropriate. Such as:

- Economic thresholds - the pest population level that inflicts crop damage greater than the cost of control
- Availability of selective pesticides
- Action levels - pest level when action should be applied to prevent pest from reaching injurious levels
- Environmental risk measurements (i.e. impacts on pollinators)
- Disease forecasting systems

IPM programmes seek to avoid pest damage through practices such as:

- Use of field sanitation and reduction of pest habitat
- Crop rotations
- Selection of pest/disease tolerant or resistant seeds and varieties
- Judicious use of pesticides that prevent pest infestations
- Resistance management

Why Practice IPM?

You might be wondering why you should even consider IPM when pesticides so often succeed at controlling pests. Here are some reasons for using a broader approach to pest management than just the use of pesticides.

- **Many IPM practices** are used before a pest problem develops to prevent or hinder the buildup of pests.
- **Keep a Balanced Ecosystem.** Every ecosystem, made up of living things and their non-living environment, has a balance; the actions of one creature in the ecosystem

usually affect other, different organisms. Many of our actions in an ecosystem can change this balance, destroying certain species and allowing other species (sometimes pests themselves) to dominate. Beneficial insects, such as the ladybird beetle and lacewing larvae, both of which consume pests, can be killed by pesticides, leaving fewer natural mechanisms of pest control.

- **Reliance on Pesticides can be Problematic.** Pesticides are not always effective when used as a singular control tactic. Pests can become resistant to pesticides. In fact, some 600 cases of pests developing pesticide resistance have been documented to date, including populations of common lamb-quarters, house flies, Colorado potato beetle, Indian meal moth, Norway rats, and greenhouse whitefly.
- **IPM Is Not Difficult.** You will have done much of the “work” for an IPM approach if you’ve figured out the problem (the pest), determined the extent of the pest population, and decided on the best combination of actions to take.
- **Maximize Effectiveness of Control Tactics.** Pest control practitioners, following traditional programs, sometimes apply pesticide treatments on a calendar based schedule regardless of the stage of development of the target pest and the number of pests present. Using an IPM approach will ensure that all control tactics, including pesticides, are used at the proper time and only to reduce pest damage to acceptable levels. This will reduce costs from unnecessary pesticide applications and insure that control tactics are used when they will be most effective.
- **Promote a Healthy Environment.** The definition of IPM promotes a careful consideration of all pest control options with protection of the environment a key goal.
- **Natural Enemies Conserved.** Parasites and predators are part of the natural control mechanism for some pest populations. These natural controls are considered and protected in an IPM program
- **Maintain a Good Public Image.** A thoughtful approach to pest control, which protects the environment and provides an abundant, affordable crop and safe living conditions, is a basic goal of IPM.

How do IPM programmes work?

IPM is not a single pest control method but, rather, a series of pest management evaluations, decisions and controls. In practicing IPM, growers who are aware of the potential for pest infestation follow a four-tiered approach. The four steps include:

- **Set Action Thresholds**

APPLIED ZOOLOGY AND LAB WORK

Before taking any pest control action, IPM first sets an action threshold, a point at which pest populations or environmental conditions indicate that pest control action must be taken. Sighting a single pest does not always mean control is needed. The level at which pests will either become an economic threat is critical to guide future pest control decisions.

- **Monitor and Identify Pests**

Not all insects, weeds, and other living organisms require control. Many organisms are innocuous, and some are even beneficial. IPM programs work to monitor for pests and identify them accurately, so that appropriate control decisions can be made in conjunction with action thresholds. This monitoring and identification removes the possibility that pesticides will be used when they are not really needed or that the wrong kind of pesticide will be used.

- **Prevention**

As a first line of pest control, IPM programs work to manage the crop, lawn, or indoor space to prevent pests from becoming a threat. In an agricultural crop, this may mean using cultural methods, such as rotating between different crops, selecting pest-resistant varieties, and planting pest-free rootstock. These control methods can be very effective and cost-efficient and present little to no risk to people or the environment.

- **Control**

Once monitoring, identification, and action thresholds indicate that pest control is required, and preventive methods are no longer effective or available, IPM programs then evaluate the proper control method both for effectiveness and risk. Effective, less risky pest controls are chosen first, including highly targeted chemicals, such as pheromones to disrupt pest mating, or mechanical control, such as trapping or weeding. If further monitoring, identifications and action thresholds indicate that less risky controls are not working, then additional pest control methods would be employed, such as targeted spraying of pesticides. Broadcast spraying of non-specific pesticides is a last resort.

8.3 BASIC CONCEPT OF PEST MANAGEMENT

History of Pest Management

- (i) 2500 BC First records of insecticides; Sumerians used sulfur compounds to control insects and mites.

- (ii) 200 BC Romans advocated oil sprays for pest control.
- (iii) 300 AD First records of biological controls; Chinese used predatory ants in citrus orchards to control caterpillar and beetle pests.
- (iv) 1880 First commercial spraying machine.
- (v) 1930 Introduction of synthetic organic compounds for plant pathogen control.
- (vi) 1940 First successful use of an entomopathogen; Milky Spore (*Bacillus popilliae*) used to control Japanese beetle.

8.4 BIOLOGICAL AND CHEMICAL CONTROL

Biological Control of Insect Pests:-

Most pests have natural enemies that control or suppress them effectively in some situations. Natural enemies, including pathogens and insects, are being used successfully as biological control agents to manage certain directed against pests that are not native to a geographical area. Introduced pests often cause problems in their new locations because they lack natural enemies to help control them. Laws have been enacted that strictly control the importation of all organisms, including biological control agents, into the United States, to prevent these organisms from also becoming pests. Biological control also involves the mass release of large numbers of natural enemies into fields, orchards, greenhouses, or other locations to control specific pests. This method usually does not have long-term results, so these natural enemies must be released periodically. Several natural enemies are reared or cultured commercially. Predatory mites are used to control plant-feeding spider mites. Parasitic wasps and lacewings are used to control various insect pests. Nematodes and fungi are being studied as biological control agents for certain weeds and some insects. General predators, such as praying mantids and lady beetles, are sold with claims made for biological control. In many cases, however, their effectiveness has not been established.

Biological pest control is the use of a living organism to control another living organism. The importance of using biological control agents to control insect and disease pests is often overlooked. Biological agents of landscape pests include.

Predators:

APPLIED ZOOLOGY AND LAB WORK

Common arthropod predators of insects include lacewings, predatory mites, minute pirate bugs, lady bird beetles and spiders. Either the adult or immature stage may prey on insect pests, so it is important to properly identify all the life stages of predator arthropods. Some predatory arthropods have greater impacts on pest populations than others. Vertebrate pest management should include the use of natural enemies. Examples include predators, such as hawks, owls and coyotes that prey on rodents. Natural enemies can be found in all habitats including landscapes, aquatic sites, and crop land and surrounding areas.

Parasites:

The life cycle of insect parasites develops in or on an insect host. The parasite feeds on body fluids or organs, usually killing the host. Common parasites include wasps, flies and nematodes. Most parasites are specialized in their choice of a host.

Weed Feeders:

Insects, grazing animals, and some fish, such as grass carp, consume plant leaves, stems, seeds, flowers and fruits. Insects are often specific to a single species of weed, while grazing animals and fish feed on a broader array of vegetation. Weed feeders seldom eradicate an infestation. However, they are useful in slowing the spread of weeds.

Pathogens:

Weeds, arthropods and vertebrate pests can be infected by pathogens, including viruses, bacteria and fungi. When environmental conditions are favourable for the pathogen, a disease outbreak can occur which may decimate the pest population. This same principle applies to disease outbreaks in all species, including humans. Most pathogens are specific to certain groups of plants or animals. A pathogen commonly found in soil is *Bacillus thuringiensis*, or “Bt”. Bt is a bacterial that is effective at controlling insects in their larval stage. It is used commercially to control mosquitoes, black flies and other insects. It is considered safe to humans and other non-target organisms. Biological control may be accomplished in one or a combination of several ways:

Conservation:

This is the process of using, protecting and encouraging existing populations of natural enemies. Examples of conservation include avoiding the use of insecticides when beneficial insect populations are high or providing nesting or roosting sites for birds of prey. Conservation is the most cost-effective form of biological control.

Augmentation:

APPLIED ZOOLOGY AND LAB WORK

This occurs when more individuals are added to an already existing population of biocontrols at a site. For instance, many species of predator and weed-feeding insects can be collected in the field or raised commercially, and may be released to increase existing populations to a level where they are effective against the pest.

Importation:

This method relies on introducing a population of beneficial organisms not currently present to a given site. This is often done to manage non-native pest species, such as the noxious weeds saltcedar and leafy spurge, or insect pests like the Russian wheat aphid.

The Nevada Department of Agriculture, in cooperation with USDA – Animal Plant Health Inspection Service (APHIS) and Plant Protection and Quarantine (PPQ) is using biological controls to manage a number of pests in Nevada.

Russian wheat aphid (*Diuraphis noxia*), a recently introduced insect, is a serious pest of barley, wheat and other small grains. Parasitic wasps, syrphid flies and different species of lady bird beetles have been released experimentally with the hope that they will contribute to the control of this damaging aphid. Attempts to control the noxious weed leafy spurge.

(*Euphorbia esula*) have included beneficial insects. Three species of flea beetle and a midge species have been released in Nevada in an attempt to decrease the population of this weed to manageable levels.

Chemical Control of Insect Pests:

Chemical controls are pesticides that are either naturally derived or synthesized. Pesticides often play a key role in pest management programmes and frequently may be the only control method available. Major benefits associated with the use of pesticides are their effectiveness, the speed and ease of controlling pests, and, in many instances, their reasonable cost compared with other control options. Usually pest damage stops or pests are destroyed within a few hours (for insects) to a few days (for weeds) after application of a pesticide. Using a fungicide may provide immediate, short term protection against microorganisms.

A pesticide is defined as any material that is applied to plants, the soil, water, harvested crops, structures, clothing and furnishings, or animals to kill, attract, repel, regulate or interrupt the growth and mating of pests, or to regulate plant growth. Pesticides include a

APPLIED ZOOLOGY AND LAB WORK

wide assortment of chemicals with specialized names and functions. They are commonly grouped according to the type of pest they control.

- **Avicides** control pest birds.
- **Bactericides** control bacteria.
- **Disinfectants (antimicrobials)** control microorganisms.
- **Fungicides** control fungi.
- **Herbicides** control weeds and other undesirable plants.
- **Insecticides** control insects and related arthropods.
- **Miticides (acaricides)** control mites.
- **Molluscicides** control snails and slugs.
- **Nematicides** control nematodes (roundworms).
- **Predacides** control predatory vertebrates.
- **Piscicides** control pest fish.
- **Repellents** repel insects, related invertebrates, birds, and mammals.
- **Rodenticides** control rodents.
- **Defoliants** cause leaves or foliage to drop from plants.
- **Desiccants** promote drying or loss of moisture from plant tissues.
- **Growth regulators** are substances (other than fertilizers or food) that alter the growth or development of a plant or animal.

Each group of pesticide includes several classes or families. For example, the classes of insecticides include, among others, the organophosphates, organochlorines, carbamates, pyrethroids, botanicals, insecticidal soaps, and microbials. The pesticides within a particular class have similar chemical structures or properties or share a common mode of action. The mode of action of a pesticide is how the pesticide works. In other words, it is what specific system in the pest is affected by the pesticide. The various classes of chemicals work in different ways and present different risks and problems.

Pesticides also vary in their selectivity. Fumigants, for example, are nonselective, controlling a wide variety of pests—fungi, insects, weeds, nematodes, etc. Some non-selective herbicides control any plant given a sufficient dose. In contrast, **selective pesticides** control only certain species of pests or affect only a certain stage of pest development. For example, certain herbicides control broadleaf weeds while not harming grasses and ovicides kill only the eggs of certain insects, mites, and related pests.

Pesticides may move in various ways after they come in contact with a host. **Systemic pesticides** are absorbed through leaves or roots and then transported within the treated plant. Similarly, systemic insecticides can be eaten by or injected into livestock to control certain pests. By contrast, **contact pesticides** are not absorbed by treated plants or animals. These pesticides must directly touch the pest or a site the pest frequents to be effective.

The use of pesticides in a proper manner and in accordance with the label. Examples of a pesticide application would include applying a dust pesticide into a wall void to control ants or using baits in a crack to control cockroaches.

Chemical controls include pesticides applied to manage pests. Pesticides should be viewed as a last-resort treatment to prevent significant damage to plants in the landscape, or as available and possibly necessary treatment for agricultural commodities or to protect human health. Pesticides are important tools, but they should be used only when necessary and in conjunction with other management tools. The development of a pest problem often signals poor management practices, so a review of the management protocols and cultural practices for a given landscape, field or property should be made prior to applying pesticides.

In the urban environment, the tendency is to use pesticides as preventative measures to ensure “perfect” landscapes. Pesticide use for this purpose is based on perceived threats from pests, but many times no actual pest has been identified and no damage is visible. Not only is this pesticide application philosophy expensive and unnecessary, it may also have significant environmental consequences. For example, over application of weed-and-feed-type products on lawns can have serious effects on adjacent ornamental plants, particularly trees planted in or adjacent to turf. The use of pesticides for structural and institutional pest control must first take into account the potential exposure to the residents of the building as well as potential health effects. When inside a structure, pesticides tend to break down more slowly than when in the outdoor environment, so residual effects must be considered. This limits the number and type of pesticides that are available for such applications. These products are highly regulated.

8.5 ELEMENTARY KNOWLEDGE OF PESTICIDES AND INTEGRATED PEST MANAGEMENT

Pesticides are designed to kill bugs that are harmful to plants. Pesticides kill specific pests on plants such as slugs, beetles and flying insects. The chemicals used in most pesticides can kill more than just garden pests; they can kill the helpful organisms that live in the soil. Some of these chemicals can remain in the soil for years, effectively keeping necessary micro-organisms from working the soil.

Common chemical pesticides that are used in gardens and by large-scale crop producers include the following:

- Basic Copper Sulfate
- Silica Gel
- Sodium Fluoride
- Carbon Disulfide
- Hydrogen Cyanide
- Methylchloroform
- Fenthion
- Boric Acid

There are literally hundreds of pesticides that have been manufactured and applied to soil in the past. We are beginning to understand the ramifications of using these toxic chemicals on the soil. In places where the chemicals are used extensively, plants will no longer grow at all, or will fail to thrive.

Types of pesticides

Many pesticides can be grouped into chemical families. Prominent insecticide families include organochlorines, organophosphates, and carbamates.

Type of Pesticide	Target Pest Group
Algicides or Algaecides	Algae
Avicides	Birds
Bactericides	Bacteria

Fungicides	Fungi and Oomycetes
Insecticides	Insects
Miticides or Acaricides	Mites
Molluscicides	Snails
Nematicides	Nematodes
Rodenticides	Rodents
Virucides	Viruses

INTEGRATED PEST MANAGEMENT

Integrated pest management, or IPM, is a system of controlling pests by combining biological, mechanical, cultural, physical and chemical control methods in a way that minimizes economic, health and environmental risks. Pests are monitored by regular and careful inspections. The inspections identify pests and the conditions contributing to the pest problems. Based on the inspection the technician then decides what actions are necessary. The knowledge of the pests biology and habits will help in determining what methods or techniques would best control the pests at the lowest potential exposure possible.

IPM as "the careful consideration of all available pest control techniques and subsequent integration of appropriate measures that discourage the development of pest populations and keep pesticides and other interventions to levels that are economically justified and reduce or minimize risks to human health and the environment.

Integrated Pest Management Stands as:-

Integrated:- A focus on interactions of pests, crops, the environment and various control methods. This approach considers all available tactics and how these tactics fit with other agricultural practices used.

Pest: - An organism that conflicts with our profit, health or convenience. If a species does not exist in numbers that seriously affect these factors, it is not considered a pest.

Management: - A way to keep the pests below the levels where they can cause economic damage. Management does not mean eradicating pests. It means finding tactics that are effective and economical, and that keep environmental damage to a minimum.

Necessity of Integrated Pest Management

For the safe and successful operation against pest population the integrated approach for pest control is required due to following reasons:

- (a) **Side effect-** The indiscriminate use of any control measure may cause harmful side effects in the environment.
- (b) **Environmental pollution-** Continuous use of any biological agent may cause unwanted change in the environment.
- (c) **Pest resurgence-** Continuous use of pesticides causes disruption of the environment and target species may recover from pesticide action.
- (d) **Pesticide resistance-** Pest may develop tolerance against pesticide being use.
- (e) **Secondary pest outbreak-** Due to application of pesticide, other non-target insects may attain the level of pest.
- (f) **Residual effect-** Pesticide residue may cause hazard to man or his pets.
- (g) **Non target species-** Pesticide being used continuously may damage useful species such as pollinators, wildlife etc.

8.6 SUMMARY

Integrated Pest Management (IPM) is an approach that emphasizes nonchemical pest prevention, focusing on facility maintenance and sanitation before considering chemical options for pest management. IPM is a multidisciplinary endeavour; it takes from branches of crop science and then assembles information from the disciplines like Agronomy, Entomology, Plant pathology, Agricultural Engineering & Climatology. The history of pest management gives us a perspective of how IPM came into being and how we have learned about effective ways to control pests. In 1967, the term “Integrated Pest Management (IPM)” was first used. Rapidly, the concept became popular to describe making informed

management decisions based on a thorough understanding of the factors that affect the pest or pests involved.

Integrated Pest Management (IPM) is the coordinated use of pest and environmental information to design and implement pest control methods that are economically, environmentally and socially sound. IPM promotes prevention over remediation and advocates integration of multiple control strategies to achieve long-term pest management solutions. IPM consists of gathering information, interpreting data, creating a flexible management plan, making timely decisions and taking the proper action. Information gathering and decision-making techniques include: accurate pest identification, learning about the weak link in a pest's life-cycle or biology, scouting and monitoring crops in fields and greenhouses, using action thresholds to minimize spraying, and keeping records of findings to assess the effectiveness of management decisions.

Along with information gathering and decision-making techniques, a variety of preventative and curative control methods are used to construct a complete IPM management plan for each pest, crop and farm. Cultural, mechanical, physical, genetic, and biological controls help prevent severe pest problems, while pesticides are used when additional control measures are required. **Cultural controls** are modifications of the crop production systems that suppress pest populations and occurrence which includes the use of better site selection, crop rotation, modifying planting times or plant spacing, improved water and nutrient management for better crop health.

Mechanical and physical controls consist of using supplies, equipment, or some factor, such as temperature, humidity or light, to disrupt pest life cycles and suppress populations by cutting, crushing, burying or excluding pests with implements and barriers, or by heating, cooling, drying, wetting, or regulating light. **Biological control** is the use of naturally occurring or introduced beneficial organisms to control or suppress pest populations. Biological control agents come in all shapes and forms including: beneficial insects, mites, spiders, nematodes, fungi, bacteria, viruses, protozoa and plants. **Pesticides** should be used in conjunction with the control measures previously mentioned and only when pest population densities will cause economic damage, or when environmental conditions favour disease. Selective insecticides are products that primarily target the pest you wish to control, with few or no detrimental effects on most beneficial. Broad-spectrum insecticides should only be used if no other viable options exist to manage the pest.

8.7 GLOSSARY

Adult Stage: The stage that is sexually mature and in which procreation occurs.

Abdomen: The posterior body division of an arthropod.

Antenna (plural: antennae): The paired segmented sensory organs, borne one on each side of the head, commonly termed horns or feelers.

Biological control: The action of parasites, predators, or pathogens in maintaining another organism's population density at a lower average level than would occur in their absence. Biological control may occur naturally in the field or result from manipulation or introduction of biological control agents by people.

Broad-spectrum pesticide: A pesticide that kills a large number of unrelated species

Diapause: A period of physiologically controlled dormancy in insects.

Economic threshold: A level of pest population or damage at which the cost of control action equals the crop value gained from control action.

Exclusion: Keeping a pest and crop separate from one another.

Frass: Solid fecal material produced by insects.

Fumigation: Treatment with a pesticide active ingredient that is a gas under treatment conditions.

Infestation: The presence of a large number of pest organisms in an area or field, on the surface of a host or anything that might contact a host, or in the soil

Instar: The larval or nymph stage of an immature insect between successive molts.

IPM: A pest management strategy that focuses on long-term prevention or suppression of pest problems through a combination of techniques.

Juvenile: Immature form of a nematode that hatches from an egg and molts several times before becoming an adult.

Larva (plural: larvae): The immature form of insects that develop through the process of complete metamorphosis including egg, several larval stages, pupa, and adult. In mites, the first-stage immature is also called a larva.

Mandibles: Jaws; the forward-most pair of mouthparts of an insect.

Meconium: Fecal pellet excreted by a larva before pupation.

Metamorphosis: The change in form that takes place as insects grow from immatures to adults.

Molt: In insects and other arthropods, the shedding of skin before entering another stage of growth.

Monitoring: Carefully watching and recording information on the activities, growth, development, and abundance of organisms or other factors on a regular basis over a period of time, often utilizing very specific procedures

Nymph: The immature stage of insects such as grasshoppers and aphids, that hatch from eggs and gradually acquire adult form through a series of molts without passing through a pupal stage.

Oviposit: To lay or deposit eggs.

Pest resurgence: The rapid rebound of a pest population after it has been controlled.

Pheromone: A substance secreted by an organism to affect the behavior or development of other members of the same species; sex pheromones that attract the opposite sex for mating are used in monitoring certain insects.

Pupa: The nonfeeding, inactive stage between larva and adult in insects with complete metamorphosis.

Quarantine: A period of enforced isolation that is required to prevent movement of undesirable organisms.

Target pest: A pest species that a control action is intended to destroy.

8.8 TERMINAL QUESTION & ANSWER

Long Answer Type Questions

1. Explain IPM & its components?
2. What is Biological control & its advantages?
3. Describe Chemical control along with its health effects?
4. What do you mean by pesticide resistant. Explain with examples?
5. Describe mechanical & physical control methods with suitable examples?

Short Answer Type Questions

1. Adjusting the planting date for a crop to avoid a pest outbreak is an example of what type of IPM practice?

Ans. Cultural control

2. What is a LD-50?

Ans. The dose of a substance that will kill 50% of a population.

3. What is the best approach for successful management of pest populations in IPM?

Ans. Monitoring, Identifying, Evaluating & Choosing

4. Why are sticky traps for insects often not a good outdoor monitoring method?

Ans. Because they attract other non target species at outdoor which produces hindrance.

5. Give realistic objective when starting an IPM program for plant disease organisms?

Ans. To plan an IPM program identify the pathogen and know its life cycle and biology.

Multiple Choice Questions

1. The three basic elements that most fertilizers contain and are displayed on the bag are:
 - a. nitrogen, phosphorous, potassium
 - b. iron, sulfur, zinc
 - c. magnesium, calcium, iron
 - d. copper, manganese, boron
2. Most pesticide poisonings occur from
 - a. inhalation
 - b. getting it on skin
 - c. swallowing
 - d. None
3. The three signal words that may be found on a pesticide label in the order of most toxic to least toxic are:
 - a. danger>caution>warning
 - b. danger>warning>caution
 - c. toxic>irritant>safe
 - d. None
4. Which of the following are practices which can be used to reduce or prevent insect pest problems?
 - a. sanitation
 - b. insecticides
 - c. crop rotation
 - d. All of the above
5. All _____ are pesticides
 - a. insecticides
 - b. fungicides
 - c. herbicides
 - d. all of the above
6. What term is used in IPM to indicate the level at which pests must be controlled?
 - a. Insect level
 - b. Disease severity

c. Action Threshold

d. Pest number

Fill in the blanks

1. IPM stands for _____
2. The 3 types of cides are _____
3. _____ attract beneficial insects to plants attacked by pests.
4. Pest control measures are best implemented before the _____ stage of the pest.
5. _____ are typically a fly or tiny wasp that develops inside another insect.

Answers

MCQ

1. a
2. b
3. b
4. d
5. d

Fill in the blanks

1. Integrated Pest Management
2. Pesticide, herbicide & insecticide
3. Insect growth regulators
4. destructive
5. Parasitoids

9.1 OBJECTIVE

The objective of this chapter is to understand the general classification of Parasites and Understand the life-cycles of the organism and their pathogenesis and transmission patterns. we will also discuss the treatment & control measures of parasitic infectons.

9.2 INTRODUCTION

A parasite is a living organism, which takes /draws its nourishment & other needs from a host; the host is an organism which supports the parasite by providing food & shelter. The study of parasites is termed as parasitology. The father of parasitology is an Italian Francesco Redi (1632-1723). Parasites are organisms which adapt them selves to live in or on other organisms termed host. A larger number of diseases are caused by several living organisms like Bacteria, Viruses, Fungi, Protozoa, and Arthropods & Helminthes. Almost all the multicellular animals are harbouring at least one protozoan parasite or the other. Parasitology is the area of biology concerned with the phenomenon of dependence of one living organism on another. A misconception about parasitic infections is that they occur only in tropical areas. Although most parasitic infections are more prevalent in the tropics, many people in temperate and subtropical areas also become infected, and visitors to tropical countries may return with a parasite infection. The parasites are antigenically and biochemically complex, as are their life histories and the pathogenesis of the diseases they cause. During their life, parasitic organisms typically go through several developmental stages that involve changes not only in structure but also in biochemical and antigenic composition. Humans are hosts to nearly 300 species of parasitic worms and over 70 species of protozoa, some derived from our primate ancestors and some acquired from the animals we have domesticated or come in contact with during our relatively short history on Earth. Disease transmitted from animals to man are known as zoonotic diseases.

Parasites can be of different kinds according to places where they live, such as –

- 1. Ectoparasite:** A parasitic organism that lives on the outer surface of its hosts.
e.g. lice, ticks, mites, etc.
- 2. Endoparasite:** A parasite that lives inside the body of their host.
e.g. Entamoeba hystolytica

3. **Facultative parasite:** An organism that exhibits both parasitic & non-parasitic modes of living & hence does not absolutely depend on the parasitic way of life, but is capable of adapting to it if placed on a host.
e.g. *Naegleria fowleri*
4. **Accidental parasite:** When a parasite attacks an unnatural host & survive.
e.g. *Hymenolepis diminuta* (rat tapeworm)
5. **Erratic parasite:** When a parasite wanders into an organ in which it is not usually found.
e.g. *Entamoeba* in the liver & lungs of humans.
6. **Monogenetic parasite:** The parasite which needs only one primary host to complete its life cycle.
e.g. *Giardia*
7. **Digenetic parasite:** The parasite which needs two hosts i.e. one primary host & one secondary host to complete its life cycle.
e.g. *Leishmania*

Similarly hosts are also of different kinds:

1. **Definitive host/ Primary host:** A host where the parasite undergoes a sexual method of reproduction.
2. **Intermediate/ Secondary host:** A host where an asexual cycle of development takes place.
3. **Reservoir host:** A host that makes the parasite available for the transmission to another host & is usually not affected by the infection.
4. **Natural host:** A host that is naturally infected with certain species of parasites.
5. **Accidental host:** The host that is under normal circumstances not affected with the parasite.
6. **Symbiosis:** Parasites may be pathogenic & non-pathogenic, there is a dynamic equilibrium which exists between the host & parasite of different species and is termed as symbiont and this relationship is called as symbiosis.
There are three common symbiotic relationships between two organisms-
 - (i) **Mutualism:** Is an association in which both partners are metabolically dependent upon each other & one cannot live without the help of the other, however, none of the partners suffer any harm from the association.

APPLIED ZOOLOGY AND LAB WORK

e.g. Certain species of flagellated protozoa living in the gut of termites. These protozoans depend entirely on carbohydrate diet, acquire it from termites & in return they synthesize cellulases which is utilized by termites in digestion.

(ii) **Commensalism:** Is an association in which the commensal takes the benefit without causing any harm to the host.

e.g. Most of the normal floras (bacteria) of the human body are commensals

(iii) **Parasitism:** Is an association where one of the partners is harmed & other lives at the expense of the other.

e.g. Schistosoma as endoparasite of man

9.3 GENERAL CHARACTER OF PARASITES

1. Parasites are found mostly in moist habitats, some free living species inhabit freshwater & marine environment where as terrestrial species inhabit decaying organic matter.
2. Parasites vary substantially in size & shape. Smaller species may be microscopic where as larger species are visible to the naked eye. Protozoan parasites have no cell wall therefore can assume any infinite variety of shapes.
3. Locomotion is done by many modes in different species i.e. by pseudopodia, cilia & flagellum in protozoans while in metazoans locomotion is done by muscular contraction & relaxation.
4. Parasites derive pre-digested nutrition directly from the host body, hence there digestive system is poorly developed or absent.
5. Nervous system of parasites is of primitive type.
6. Respiration in parasites takes place through diffusion or general body surface as they reside inside the host where oxygen availability is less.
7. Excretion in protozoans takes place through vacuoles where as in metazoans through specialised organs.
8. Parasites can be both monoecious & diecious. Protozoans reproduce through asexual method by binary fission where as metazoans reproduce by sexual method.
9. Reproduction rate is very high in parasites as they produces high no of eggs in very short time.
10. Fertilization is external.

11. Development is indirect with immature larval stages which are motile, feeding & independent.
12. Cleavage is spiral.
13. Presence of protective covering to withstand harsh environmental conditions such as envelope or cyst in protozoans where as cuticle or tegument in metazoans.
14. Presence of adhesive structures in parasites to remain at the specific site of infection such as suckers, hooks, rostellum.

9.4 DISEASE CAUSED AND CONTROL MEASURE OF E.HISTOLYTICA

ENTAMOEBEA

Systematic Position

Phylum- Protozoa

Subphylum- Sarcomastigophora

Supesclass- Sarcodina

Class- Rhizopodea

Subclass- Lobosia

Order- Amoebida

Genus- *Entamoeba*

Species- *histolytica*

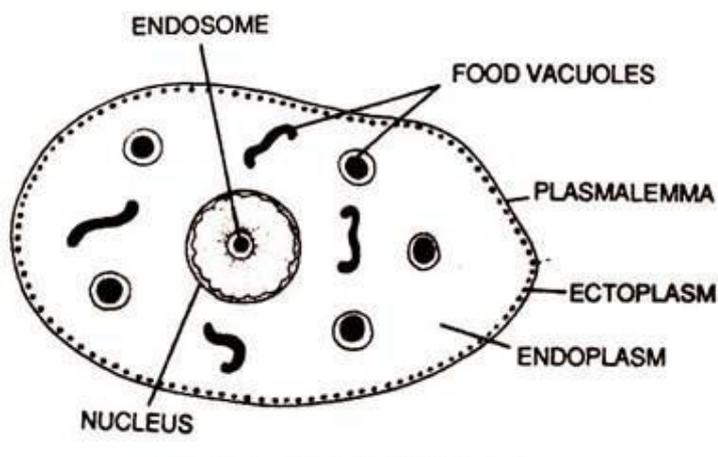

Fig 9.1 Entamoeba hystolytica

Entamoeba histolytica is a protozoan parasite responsible for a disease called amoebiasis. It occurs usually in the large intestine and causes internal inflammation as its name suggests (histo = tissue, lytic = destroying). 50 million people are infected worldwide, mostly in tropical countries in areas of poor sanitation. In industrialized countries most of the infected patients are immigrants, institutionalized people and those who have recently visited developing countries.

General Characters

1. It is found mainly in tropics & subtropics in addition to that higher in rural and densely populated urban areas.
2. It is a monogenetic parasite which affects mainly children's and young adults.

APPLIED ZOOLOGY AND LAB WORK

3. It is a microscopic endoparasite of man that is commonly found in the upper part of the large intestine.
4. It occurs in three distinct forms i.e. Trophozoite/magna form, precystic /minuta form and cystic form.
5. It is holozoic in nature and feed by phagocytosis.
6. Encystation i.e. formation of a cyst wall during unfavourable environmental conditions is an adaptation by this parasite to thrive in harsh conditions.
7. It reproduces asexually by binary fission.
8. Metacyst is the infective stage of parasite.
9. It causes Amoebic dysentery disease.

Inside humans *Entamoeba histolytica* lives and multiplies as a trophozoite. Trophozoites are oblong and about 15–20 μm in length. In order to infect other humans they encyst and exit the body. The **life cycle** of *Entamoeba histolytica* does not require any intermediate host. Mature cysts (spherical, 12–15 μm in diameter) are passed in the feces of an infected human. Another human can get infected by ingesting them in fecally contaminated water, food or hands. If the cysts survive the acidic stomach, they transform back into trophozoites in the small intestine. Trophozoites migrate to the large intestine where they live and multiply by binary fission. Both cysts and trophozoites are sometimes present in the feces. Cysts are usually found in firm stool, whereas trophozoites are found in loose stool. Only cysts can survive longer periods (up to many weeks outside the host) and infect other humans. If trophozoites are ingested, they are killed by the gastric acid of the stomach. Occasionally trophozoites might be transmitted during sexual intercourse.

LIFE CYCLE

It is a monogenetic parasite. Its life cycle concludes within a primary host i.e. man. Inside humans *Entamoeba histolytica* lives and multiplies as a trophozoite. Trophozoites are oblong and about 15–20 μm in length. Trophozoites multiply asexually by binary fission inside the wall of large intestine, which grow rapidly in size feeding upon bacteria and host tissue. In order to infect other humans they encyst and exit the body. Mature cysts (spherical, 12–15 μm in diameter) are passed in the feces of an infected human. Transmission of the parasite takes place by the intake of contaminated food & water with faecal matter containing tetra nucleate cyst. The cystic or minuta form is excreted out with faeces which infect new host when ingested and pass down the alimentary canal & reach small intestine. After 5-6 hours excystation takes place thereby releasing tetra nucleate amoeba, called the excystic amoeba

APPLIED ZOOLOGY AND LAB WORK

or metacyst. These metacyst immediately start dividing to produce 8 small uninucleate amoebulae or metacystic trophozoites, which invade intestine mucous lining & grow into mature trophozoites. Both cysts and trophozoites are sometimes present in the feces. Cysts are usually found in firm stool, whereas trophozoites are found in loose stool. Only cysts can survive longer periods (up to many weeks outside the host) and infect other humans. If trophozoites are ingested, they are killed by the gastric acid of the stomach. Occasionally trophozoites might be transmitted during sexual intercourse.

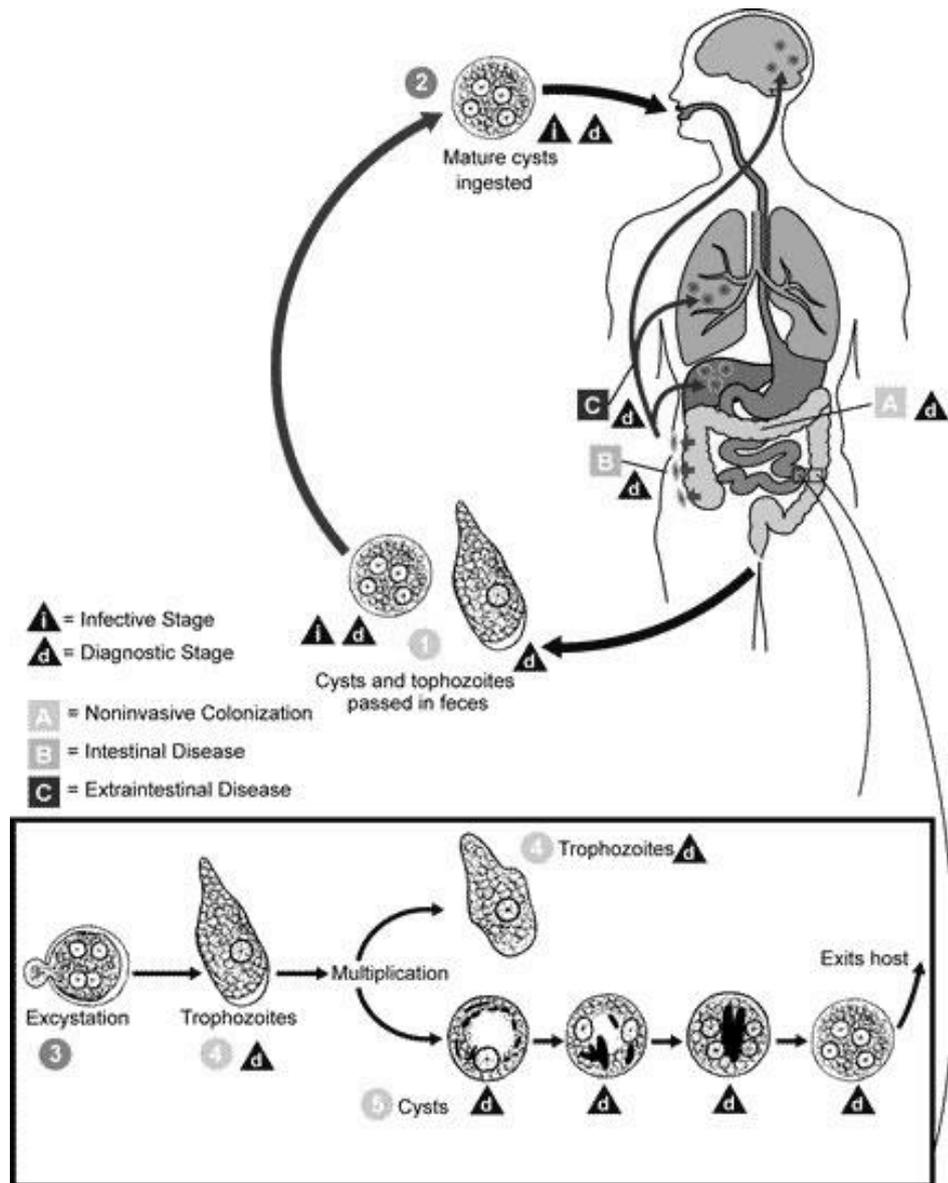

Fig9.2. Life Cycle

PATHOGENECITY

APPLIED ZOOLOGY AND LAB WORK

Several protozoan species in the genus *Entamoeba* colonize humans, but not all of them are associated with disease. *Entamoeba histolytica* is well recognized as a pathogenic amoeba, associated with intestinal and extraintestinal infections. The other species are important because they may be confused with *E. histolytica* in diagnostic investigations.

Entamoeba histolytica causes Amoebiasis or Amoebic dysentery. It causes ulcers which are flask shaped containing lymphocytes, blood corpuscles, cellular debris and bacteria which lead to formation of cavity filled with pus. The blood and ulcer contents pass outside with the stool. Infected person's stool is usually acidic and consists of swarms of amoeba which causes the new infection. Sometimes trophozoites make their way through blood circulation into brain, liver, spleen, lungs and gonads where they destroy tissues.

Symptoms of these more **severe infections** include:

- anemia
- appendicitis (inflammation of the appendix)
- bloody diarrhea
- fatigue
- fever
- gas (flatulence)
- genital and skin lesions
- intermittent constipation
- liver abscesses (can lead to death, if not treated)
- malnutrition
- painful defecation (passage of the stool)
- peritonitis (inflammation of the peritoneum which is the thin membrane that lines the abdominal wall)
- pleuropulmonary abscesses
- stomach ache
- stomach cramping
- toxic megacolon (dilated colon)
- weight loss.

Prevention

To **prevent** spreading the infection to others, one should take care of personal hygiene. Always wash your hands with soap and water after using the toilet and before eating or

preparing food. Amoebiasis is common in developing countries. Some good practices, when visiting areas of poor sanitation:

- Wash your hands often.
- Avoid eating raw food.
- Avoid eating raw vegetables or fruit that you did not wash and peel yourself.
- Avoid consuming milk or other dairy products that have not been pasteurized.
- Drink only bottled or boiled water or carbonated (bubbly) drinks in cans or bottles.

Natural water can be made safe by filtering it through an "absolute 1 micron or less" filter and dissolving iodine tablets in the filtered water. "Absolute 1 micron" filters are found in outdoor/camping supply stores.

Diagnosis

Amoebiasis is diagnosed by your health care provider under a microscope by finding cysts and (rarely trophozoites) from a stool sample. The results are usually said to be negative, if *Entamoeba histolytica* is not found in three different stool samples. But it still does not necessarily mean that you are not infected because the microscopic parasite is hard to find and it might not be present the particular samples. A blood test might also be available but is only recommended, if your health care provider believes that the infection could have spread to other parts of the body. Trophozoites can be identified under a microscope from biopsy samples taken during colonoscopy or surgery.

Entamoeba histolytica should be differentiated from the non-pathogenic *Entamoeba dispar*. The two are morphologically identical and differentiation must be based on immunologic or isoenzymatic analysis or molecular methods. They can be distinguished under a microscope, if *Entamoeba histolytica* has ingested red blood cells. *Entamoeba dispar* is about 10 times more common. If either one is found, then you are usually treated.

Treatment

If you are experiencing amoebiasis symptoms, you are treated with two antibiotics. The preferred drugs are metronidazole or tinidazole immediately followed with paromomycin, diloxanide furoate or iodoquinol. Asymptomatic intestinal amoebiasis is treated with paromomycin, diloxanide furoate or iodoquinol.

9.5 TRYPANOSOMA

Systematic Position

Phylum- Protozoa

Subphylum- Sarcomastigophora

Supesclass- Mastigophora

Class- Zoomastigophorea

Order- Kinetoplastida

Genus- *Trypanosoma*

Species- *gambiense*

GENERAL CHARACTERS

- It is found mainly in South East Asia, Central & West Africa.
- Trypanosomes are essentially found near moist places.
- Trypanosoma is a monophyletic group of unicellular parasitic flagellate protozoa characterized by possession of a flagellum near posterior end of body.
- Trypanosomes infect a variety of hosts & cause various diseases.
- Polymorphism is shown by trypanosomes on the basis of position of kinetoplast & blepharoplast and the course taken by the flagellum.
- Trypanosomes are heteroxenous i.e. requiring more than one obligatory host to complete its life cycle.
- They are mostly transmitted via a vector.
- Majority of trypanosomes are blood feeding invertebrates.
- Inside an invertebrate host they are generally found in intestine where as in a mammalian host they occupy blood stream.
- It is microscopic, elongated, leaf like tapering at both ends.
- The anterior end contains the free flagellum where as posterior end is blunt.
- Whole body is externally surrounded by thin, elastic covering called pellicle.
- Undulating membrane is an adaptation for locomotion inside the host body. It is a membranous fold which is attached to the pellicle originating from the flagellum.
- Cytoplasm is enclosed within the pellicle.

- Nucleus is large, oval & vesicular within the cytoplasm.
- It reproduces asexually by longitudinal binary fission.
- The long & slender trypanosomes show adaptations to antibodies produced by host body & continue to survive and multiply.

Trypanosomiasis, also known as "sleeping sickness," is caused by microscopic parasites of the species *Trypanosoma brucei*. It is transmitted by the tsetse fly (*Glossina* species), which is found only in rural Africa. Although the infection is not found in the United States, historically, it has been a serious public health problem in some regions of sub-Saharan Africa. Currently, about 10,000 new cases each year are reported to the World Health organization; however, it is believed that many cases go undiagnosed and unreported. Sleeping sickness is curable with medication, but is fatal if left untreated.

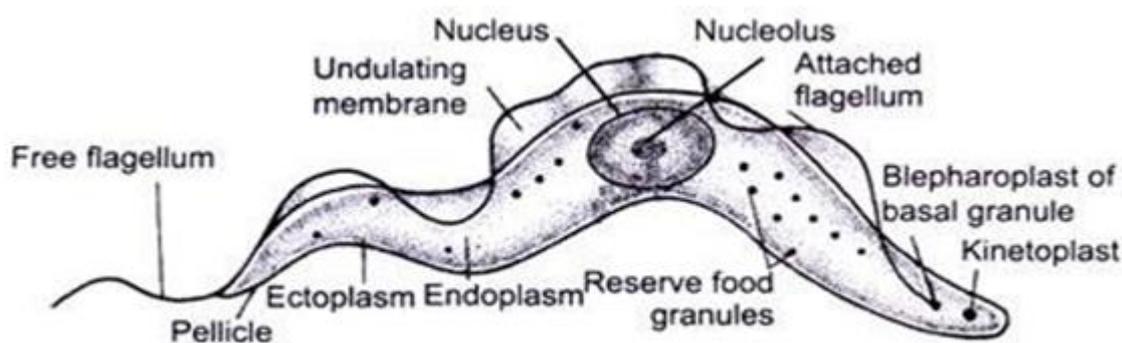

Fig 9.3 *Trypanosoma*

LIFE-CYCLE

Trypanosoma exhibits polymorphism *i.e.* occur in four morphological forms which are-

Leishmanial (Amastigote) form: It is round or oval with a nucleus, blepharoplast & kinetoplast. Flagellum reduced and fibril like embedded in cytoplasm.

Leptomonad (Promastigote) form: Body elongated nucleus large & anteriorly located blepharoplast and kinetoplast. Flagellum short & unattached.

Crithidial (epimastigote) form: Body elongate, blepharoplast & kinetoplast placed immediately anterior to nucleus. Undulating membrane inconspicuous. Crithidial form is represented only in salivary glands of tse-tse fly.

Trypanosomid (Trypomastigote) form: Elongate body with blepharoplast & kinetoplast situated near the posterior end. Undulating membrane conspicuous.

Trypanosoma is digenetic that is completes its life cycle in two hosts. The primary host is man and the secondary host is a blood sucking insect called tsetse fly (*Glossina palpalis*). The infection to humans by trypanosomes is transmitted by the bite of tsetse fly which contains infective metacyclic forms in salivary glands. The tsetse fly feeding upon mammalian blood releases the contaminated trypanosomes into his blood stream. All stages of trypanosome in human are extracellular i.e. present in the blood plasma. The vector takes in short stumpy forms along with the blood which continue to develop inside it into long slender forms & multiply by asexual method. After transformation inside vector they move into its mouth region & metamorphose into crithidial forms having shortened body, reduced flagellum. The crithidial form further transform into slender metacyclic non-motile form which is the infective stage.

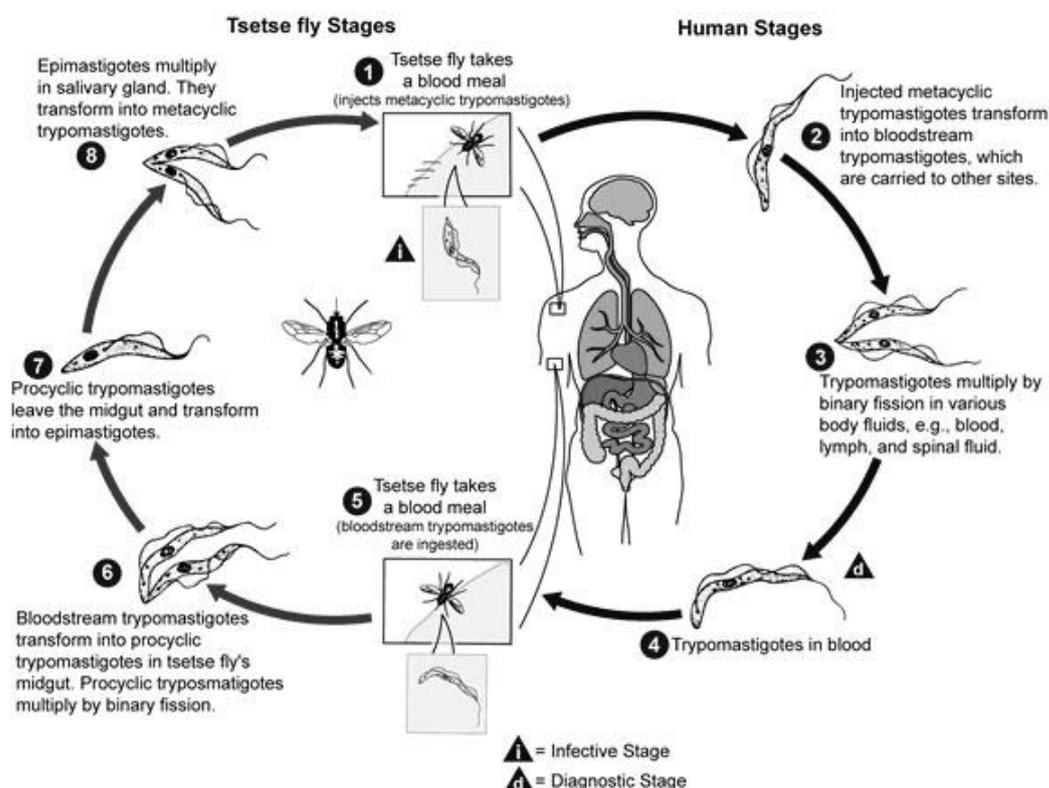

Fig: 9.4 Life Cycle of Trypanosoma

During a blood meal on the mammalian host, an infected tsetse fly (genus *Glossina*) injects metacyclic trypomastigotes into skin tissue. The parasites enter the lymphatic system and pass into the bloodstream. Inside the host, they transform into bloodstream trypomastigotes, are carried to other sites throughout the body, reach other blood fluids (e.g., lymph, spinal fluid), and continue the replication by binary fission. The entire life cycle of African Trypanosomes is represented by extracellular stages. The tsetse fly becomes infected with bloodstream trypomastigotes when taking a blood meal on an infected mammalian host. In

APPLIED ZOOLOGY AND LAB WORK

the fly's midgut, the parasites transform into procyclic trypomastigotes, multiply by binary fission, leave the midgut, and transform into epimastigotes. The epimastigotes reach the fly's salivary glands and continue multiplication by binary fission. The cycle in the fly takes approximately 3 weeks. Humans are the main reservoir for *Trypanosoma brucei gambiense*, but this species can also be found in animals. Wild game animals are the main reservoir of *T. b. rhodesiense*.

PATHOGENECITY

Protozoan hemo flagellates belonging to the complex *Trypanosoma brucei*. Two subspecies that are morphologically indistinguishable cause distinct disease patterns in humans: *T. b. gambiense* causes West African sleeping sickness and *T. b. rhodesiense* causes East African sleeping sickness. (A third member of the complex, *T. b. brucei*, under normal conditions does not infect humans.)

Trypanosomes cause Gambian trypanosomiasis /Sleeping sickness in man. The metacyclic promastigote are introduced subcutaneously by the bite of tsetse fly & multiply in 2-3 days. There is itching, swelling, pain & redness developed at the site where vector bites. The earliest sign of generalized infection is loss of weight, fever followed by headache & pain in the joints. 5-12 days after infection the parasite is found in the blood stream swimming freely. Special character of disease is enlargement of cervical lymph nodes called as winterbottom's sign. The disease sleeping sickness is caused when parasites invade cerebrospinal fluid of central nervous system.

The clinical course of human African trypanosomiasis has two stages. In the first stage, the parasite is found in the peripheral circulation, but it has not yet invaded the central nervous system. Once the parasite crosses the blood-brain barrier and infects the central nervous system, the disease enters the second stage. The subspecies that cause African trypanosomiasis have different rates of disease progression, and the clinical features depend on which form of the parasite (*T. b. rhodesiense* or *T. b. gambiense*) is causing the infection. However, infection with either form will eventually lead to coma and death if not treated.

T. b. rhodesiense infection (East African sleeping sickness) progresses rapidly. In some patients, a large sore (a chancre) will develop at the site of the tsetse bite. Most patients develop fever, headache, muscle and joint aches, and enlarged lymph nodes within 1-2 weeks of the infective bite. Some people develop a rash. After a few weeks of infection, the parasite

invades the central nervous system and eventually causes mental deterioration and other neurologic problems. Death ensues usually within months.

T. b. gambiense infection (West African sleeping sickness) progresses more slowly. At first, there may be only mild symptoms. Infected persons may have intermittent fevers, headaches, muscle and joint aches, and malaise. Itching of the skin, swollen lymph nodes, and weight loss can occur. Usually, after 1-2 years, there is evidence of central nervous system involvement, with personality changes, daytime sleepiness with nighttime sleep disturbance, and progressive confusion. Other neurologic signs, such as partial paralysis or problems with balance or walking may occur, as well as hormonal imbalances. The course of untreated infection rarely lasts longer than 6-7 years and more often kills in about 3 years.

DIAGNOSIS

The diagnosis of African Trypanosomiasis is made through laboratory methods, because the clinical features of infection are not sufficiently specific. The diagnosis rests on finding the parasite in body fluid or tissue by microscopy. The parasite load in *T. b. rhodesiense* infection is substantially higher than the level in *T. b. gambiense* infection.

T. b. rhodesiense parasites can easily be found in blood. They can also be found in lymph node fluid or in fluid or biopsy of a chancre. Serologic testing is not widely available and is not used in the diagnosis, since microscopic detection of the parasite is straightforward.

The classic method for diagnosing *T. b. gambiense* infection is by microscopic examination of lymph node aspirate, usually from a posterior cervical node. It is often difficult to detect *T. b. gambiense* in blood. Concentration techniques and serial examinations are frequently needed. Serologic testing is available outside the U.S. for *T. b. gambiense*; however, it normally is used for screening purposes only and the definitive diagnosis rests on microscopic observation of the parasite.

All patients diagnosed with African trypanosomiasis must have their cerebrospinal fluid examined to determine whether there is involvement of the central nervous system, since the choice of treatment drug(s) will depend on the disease stage. The World Health Organization criteria for central nervous system involvement include increased protein in cerebrospinal fluid and a white cell count of more than 5. Trypanosomes can often be observed in cerebrospinal fluid in persons with second stage infection.

TREATMENT

All persons diagnosed with African Trypanosomiasis should receive treatment. The specific drug and treatment course will depend on the type of infection (*T. b. gambiense* or *T. b. rhodesiense*) and the disease stage (i.e. whether the central nervous system has been invaded by the parasite). Pentamidine, which is the recommended drug for first stage *T. b. gambiense* infection, is widely available in the U.S. The other drugs (suramin, melarsoprol, eflornithine, and nifurtimox) used to treat African trypanosomiasis are available in the U.S. only from the CDC. Physicians can consult with CDC staff for advice on diagnosis and management and to obtain otherwise unavailable treatment drug.

There is no test of cure for African trypanosomiasis. After treatment patients need to have serial examinations of their cerebrospinal fluid for 2 years, so that relapse can be detected if it occurs.

PREVENTION & CONTROL

There is no vaccine or drug for prophylaxis against African trypanosomiasis. Preventive measures are aimed at minimizing contact with tsetse flies. Local residents are usually aware of the areas that are heavily infested and they can provide advice about places to avoid. Other helpful measures include:

- Wear long-sleeved shirts and pants of medium-weight material in neutral colors that blend with the background environment. Tsetse flies are attracted to bright or dark colors, and they can bite through lightweight clothing.
- Inspect vehicles before entering. The flies are attracted to the motion and dust from moving vehicles.
- Avoid bushes. The tsetse fly is less active during the hottest part of the day but will bite if disturbed.
- Use insect repellent. Permethrin-impregnated clothing and insect repellent have not been proved to be particularly effective against tsetse flies, but they will prevent other insect bites that can cause illness.

Control of African trypanosomiasis rests on two strategies: reducing the disease reservoir and controlling the tsetse fly vector. Because humans are the significant disease reservoir for *T. b. gambiense*, the main control strategy for this subspecies is active case-finding through population screening, followed by treatment of the infected persons that are identified. Tsetse fly traps are sometimes used as an adjunct. Reducing the reservoir of infection is more difficult for *T. b. rhodesiense*, since there are a variety of animal hosts. Vector control is the

primary strategy in use. This is usually done with traps or screens, in combination with insecticides and odors that attract the flies.

9.6 LEISHMANIA

Systematic Position

Phylum- Protozoa

Subphylum- Sarcomastigophora

Supesclass- Mastigophora

Class- Zoomastigophorea

Order- Kinetoplastida

Genus- *Leishmania*

Species- *donovani*

GENERAL CHARACTERS

- It is a digenetic protozoan parasite which needs two hosts to complete its life cycle.
- It occurs mainly in temperate zones of the world.
- Its primary host is mammal/man where as secondary host is blood sucking sand fly.
- It lives inside the intestine & visceral organs like spleen, bone marrow, liver & lymph glands.
- Body of the parasite is covered externally by protective covering called pellicle.
- Undulating membrane is absent.
- It shows dimorphism i.e. occurs in two forms in its life cycle which are –
- Leishmanial /Amastigote form: This form is non-motile, smaller, round & oval which lives inside the primary host man in its blood cells.
- Leptomonad/ Promastigote form: This form is motile, long, elongated, slender & spindle shaped with a flagellum.
- It reproduces asexually by longitudinal binary fission.
- In order to avoid destruction by the immune system & thrive, it hides inside the hosts cells.
- It resides inside man in the reticuloendothelial system of the viscera, where amastigote form multiplies until the host cell is destroyed.
- It causes the disease black fever / kala azar.

Two developmental stages are formed: amastigotes and promastigotes. The amastigotes are small spherical non-flagellated cells ranging from 2-4 μ m in diameter. The nucleus and kinetoplast are surrounded by small ring of vacuolated cytoplasm and the cells are among the smallest nucleated cells known. Promastigotes are thin elongate cells with an anterior kinetoplast and an emergent free flagellum. They are generally lance-like in shape and range in size from 5-14 μ m in length by 1.5-3.5 μ m in width. Different parasite species are generally not differentiated by morphological differences, but rather on the basis of geographical, biological and clinical features.

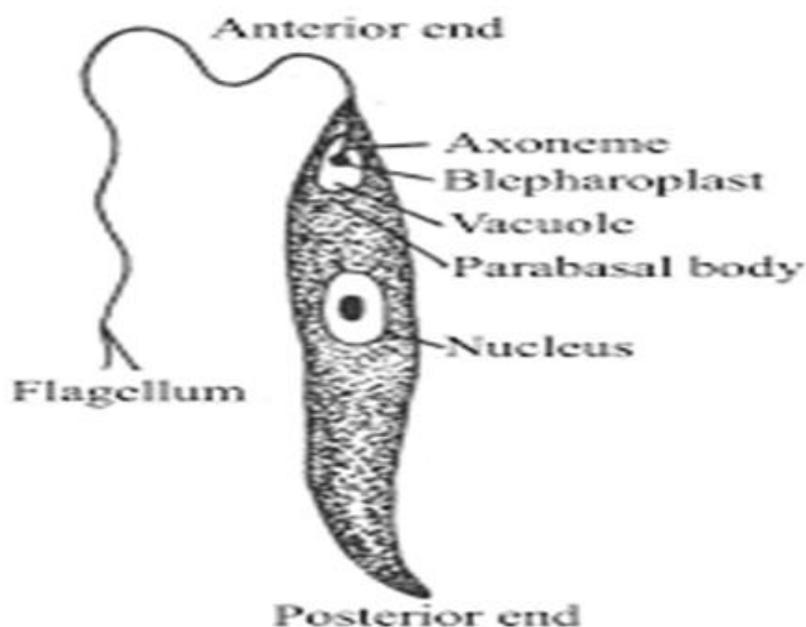

Fig. 9.5 *Leishmania donovani*

Leishmaniasis is a parasitic disease that is found in parts of the tropics, subtropics, and southern Europe. It is classified as a Neglected Tropical Disease (NTD). Leishmaniasis is caused by infection with *Leishmania* parasites, which are spread by the bite of phlebotomine sand flies. There are several different forms of leishmaniasis in people. The most common forms are **cutaneous leishmaniasis**, which causes skin sores, and **visceral leishmaniasis**, which affects several internal organs (usually spleen, liver, and bone marrow).

LIFE –CYCLE

Since the parasite is digenetic therefore it needs two hosts for completion of its life cycle i.e. primary host is man where as secondary host is blood sucking invertebrate sand fly (*Phlebotomus*).

APPLIED ZOOLOGY AND LAB WORK

- (i) In Human: It is transmitted by the bite of vector, firstly before entrance they are in the form of promastigote/ leptomonad but after infection changes into amastigote/ leishmanial form & undergo slow multiplication after which they reside in liver, spleen, bone marrow & lymph nodes where their number increases from few to several hundred inside the host cell and ruptures liberating parasites which infect new cells.
- (ii) In Invertebrate/Vector: The parasite enters the invertebrate in amastigote form. It feeds upon an infected person blood. This form further develops inside vector's midgut and get elongated to form a flagellum, where they increases in number & migrate to pharynx & now are ready to infect new person when vector finds new host.

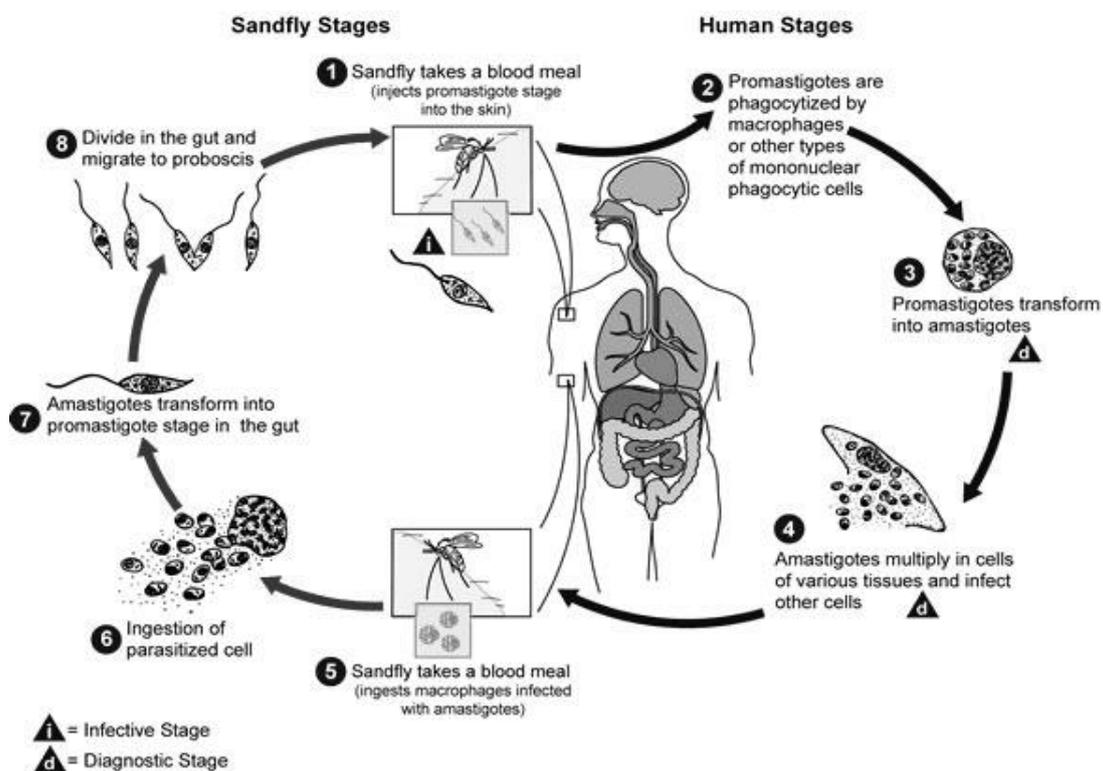

Fig 9.6 Life Cycles

Leishmania is transmitted by the bite of infected female phlebotomine sandflies. The sandflies inject the infective stage (*i.e.*, promastigotes) from their proboscis during blood meals. Promastigotes that reach the puncture wound are phagocytized by macrophages and other types of mononuclear phagocytic cells. Promastigotes transform in these cells into the tissue stage of the parasite (*i.e.*, amastigotes), which multiply by simple division and proceed to infect other mononuclear phagocytic cells. Parasite, host, and other factors affect whether the infection becomes symptomatic and whether cutaneous or visceral leishmaniasis results. Sandflies become infected by ingesting infected cells during blood meals. In sandflies, amastigotes transform into promastigotes, develop in the gut (in the hindgut for leishmanial

organisms in the *Viannia* subgenus; in the midgut for organisms in the *Leishmania* subgenus), and migrate to the proboscis.

PATHOGENECITY

Leishmaniasis is a vector-borne disease that is transmitted by sandflies and caused by obligate intracellular protozoa of the genus *Leishmania*. Human infection is caused by about 21 of 30 species that infect mammals. These include the *L. donovani* complex with 2 species (*L. donovani*, *L. infantum* [also known as *L. chagasi* in the New World]); the *L. mexicana* complex with 3 main species (*L. mexicana*, *L. amazonensis*, and *L. venezuelensis*); *L. tropica*; *L. major*; *L. aethiopica*; and the subgenus *Viannia* with 4 main species (*L. (V.) braziliensis*, *L. (V.) guyanensis*, *L. (V.) panamensis*, and *L. (V.) peruviana*). The different species are morphologically indistinguishable, but they can be differentiated by isoenzyme analysis, molecular methods, or monoclonal antibodies.

This parasite cause's disease black fever also known as Kala-azar as its name suggests during the disease the skin of patient becomes dark, rough which gives black appearance. Symptoms begin with intermittent fever, weakness, and diarrhea; chills and sweating that may resemble malaria symptoms are also common early in the infection. As organisms proliferate & invade cells of the liver and spleen, marked enlargement of the organs, weight loss, anemia, and emaciation occurs. With persistence of the disease, deeply pigmented, granulomatous lesion of skin, referred to as post-kala-azar dermal leishmaniasis, occurs. The organs of the reticuloendothelial system (liver, spleen and bone marrow) are the most severely affected organs. Reduced bone marrow activity, coupled with cellular distraction in the spleen, results in anaemia, leukopenia and thrombocytopenia. This leads to secondary infections and a tendency to bleed.

There are several different forms of leishmaniasis in people. The most common form is **Cutaneous leishmaniasis**: This causes skin sores. The sores typically develop within a few weeks or months of the sand fly bite. The sores can change in size and appearance over time. The sores may start out as papules (bumps) or nodules (lumps) and may end up as ulcers (like a volcano, with a raised edge and central crater); skin ulcers might be covered by scab or crust. The sores usually are painless but can be painful. Some people have swollen glands near the sores (for example, under the arm, if the sores are on the arm or hand).

Visceral leishmaniasis: which affects several internal organs (usually spleen, liver, and bone marrow) and can be life threatening. The illness typically develops within months (sometimes as long as years) of the sand fly bite. Affected people usually have fever, weight loss, enlargement (swelling) of the spleen and liver, and low blood counts—a low red blood cell count (anemia), a low white blood cell count (leukopenia), and a low platelet count (thrombocytopenia).

Mucosal leishmaniasis is an example of one of the less common forms of leishmaniasis. This form can be a sequela (consequence) of infection with some of the species (types) of the parasite that cause cutaneous leishmaniasis in parts of Latin America: certain types of the parasite might spread from the skin and cause sores in the mucous membranes of the nose (most common location), mouth, or throat. The best way to prevent mucosal leishmaniasis is to ensure adequate treatment of the original cutaneous (skin) infection.

DIAGNOSIS

Various laboratory methods can be used to diagnose leishmaniasis—to detect the parasite as well as to identify the *Leishmania* species (type). Some of the methods are available only in reference laboratories. In the United States, CDC staff can assist with the testing for leishmaniasis.

Tissue specimens—such as from skin sores (for cutaneous leishmaniasis) or from bone marrow (for visceral leishmaniasis)—can be examined for the parasite under a microscope, in special cultures, and in other ways. Blood tests that detect antibody (an immune response) to the parasite can be helpful for cases of visceral leishmaniasis; tests to look for the parasite itself usually also are done.

TREATMENT

Before considering treatment, the first step is to make sure the diagnosis is correct. Treatment decisions should be individualized. Health care providers may consult CDC staff about the relative merits of various approaches. Examples of factors to consider include the form of leishmaniasis, the *Leishmania* species that caused it, the potential severity of the case, and the patient's underlying health.

The skin sores of **cutaneous leishmaniasis** usually heal on their own, even without treatment. But this can take months or even years, and the sores can leave ugly scars. Another potential concern applies to some (not all) types of the parasite found in parts of Latin

APPLIED ZOOLOGY AND LAB WORK

America: certain types might spread from the skin and cause sores in the mucous membranes of the nose (most common location), mouth, or throat (**mucosal leishmaniasis**). Mucosal leishmaniasis might not be noticed until years after the original sores healed. The best way to prevent mucosal leishmaniasis is to ensure adequate treatment of the cutaneous infection. If not treated, severe (advanced) cases of **visceral leishmaniasis** typically are fatal.

PREVENTION & CONTROL

No vaccines or drugs to prevent infection are available. The best way for travelers to prevent infection is to protect themselves from sand fly bites. To decrease the risk of being bitten, follow these preventive measures:

Avoid outdoor activities, especially from dusk to dawn, when sand flies generally are the most active.

When outdoors (or in unprotected quarters):

- Minimize the amount of exposed (uncovered) skin. To the extent that is tolerable in the climate, wear long-sleeved shirts, long pants, and socks; and tuck your shirt into your pants. (See below about wearing insecticide-treated clothing).
- Apply insect repellent to exposed skin and under the ends of sleeves and pant legs. Follow the instructions on the label of the repellent. The most effective repellents generally are those that contain the chemical DEET (N, N-diethylmetatoluamide).

Note:-

Bed nets, repellents, and insecticides should be purchased before traveling and can be found in hardware, camping, and military surplus stores. Bed nets and clothing that already have been treated with a pyrethroid-containing insecticide also are commercially available.

When Indoors:

- Stay in well-screened or air-conditioned areas.
- Keep in mind that sand flies are much smaller than mosquitoes and therefore can get through smaller holes.
- Spray living/sleeping areas with an insecticide to kill insects.
- If you are not sleeping in a well-screened or air-conditioned area, use a bed net and tuck it under your mattress. If possible, use a bed net that has been soaked in or sprayed with a pyrethroid-containing insecticide. The same treatment can be applied to screens, curtains, sheets, and clothing (clothing should be retreated after five washings).

9.7 GIARDIA

Systematic Position

Phylum- Protozoa

Subphylum- Sarcomastigophora

Supesclass- Mastigophora

Class- Zoomastigophorea

Order- Diplomonadida

Genus- *Giardia*

Species- *lamblia*

Giardia intestinalis is a protozoan flagellate (Diplomonadida). This protozoan was initially named *Cercomonas intestinalis* by Lambl in 1859. It was renamed *Giardia lamblia* by Stiles in 1915 in honor of Professor A. Giard of Paris and Dr. F. Lambl of Prague. However, many consider the name, *Giardia intestinalis*, to be the correct name for this protozoan.

General characters

- *Giardia* is commonly called as 'Grand Old Man of the Intestine'.
- It is found mainly in tropics & subtropics.
- It is a monogenetic diplomonad flagellate protozoan parasite.
- It is cosmopolitan in nature.
- It is found as a parasite in digestive tract of man.
- It is similar to shape in Entamoeba.
- It bears four flagella on each side.
- It is bilaterally symmetrical, pear-shaped with two nuclei.
- Transmission is by ingestion of the infective cyst.
- It exhibits polymorphism .i.e. two distinct forms.
- The life cycle consists of two stages, the trophozoite and cyst.
- It reproduces by binary fission
- It causes disease Giardiasis.

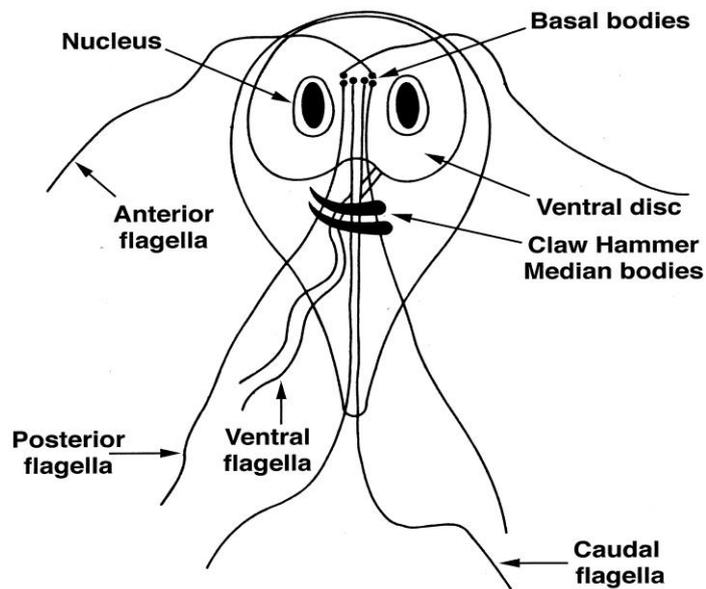

Fig 9.7 Giardia

LIFE –CYCLE

Infection with *Giardia* is initiated by ingestion of cysts. Each cyst gives rise to two trophozoites during excystation in the intestinal tract. Gastric acid stimulates excystation, with the release of trophozoites in duodenum and jejunum. The trophozoite is the feeding form motile & pathogenic, it is somewhat pear shaped which get attach to the intestinal villi by the ventral sucking discs and start feeding upon mucous secretions till they attain maturity. After maturation they multiply by longitudinal binary fission and transform into cystic form. It is the infective stage which is round & oval in shape; get passed out with the faeces. Ready to be ingested along with contaminated water & food by a new host to cause a new infection.

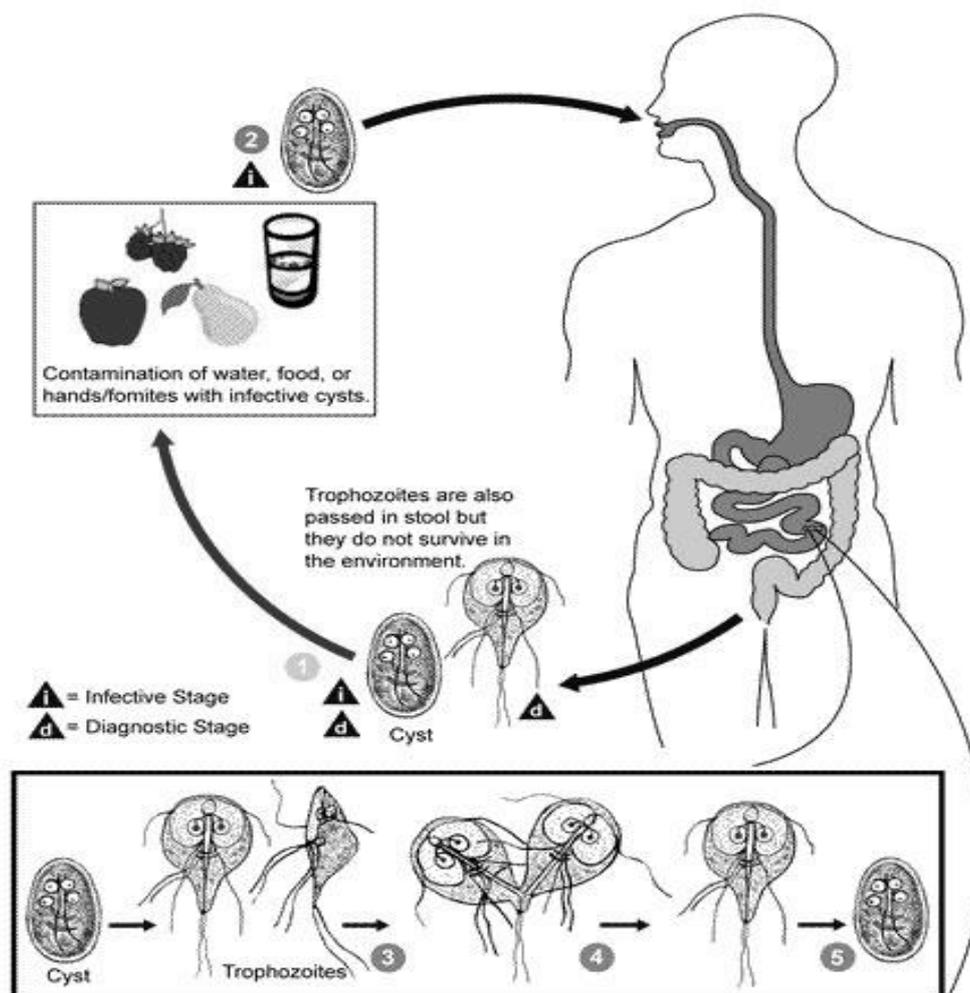

Fig 9.8 Life Cycle of Giardia

Cysts are resistant forms and are responsible for transmission of giardiasis. Both cysts and trophozoites can be found in the feces (diagnostic stages) (1). The cysts are hardy and can survive several months in cold water. Infection occurs by the ingestion of cysts in contaminated water, food, or by the fecal-oral route (hands or fomites) (2). In the small intestine, excystation releases trophozoites (each cyst produces two trophozoites) (3). Trophozoites multiply by longitudinal binary fission, remaining in the lumen of the proximal small bowel where they can be free or attached to the mucosa by a ventral sucking disk (4). Encystation occurs as the parasites transit toward the colon. The cyst is the stage found most commonly in nondiarrheal feces (5). Because the cysts are infectious when passed in the stool

or shortly afterward, person-to-person transmission is possible. While animals are infected with *Giardia*, their importance as a reservoir is unclear.

Diagnosis & Detection

Because *Giardia* cysts can be excreted intermittently, multiple stool collections (i.e., three stool specimens collected on separate days) increase test sensitivity. The use of concentration methods and trichrome staining might not be sufficient to identify *Giardia* because variability in the concentration of organisms in the stool can make this infection difficult to diagnose. For this reason, fecal immunoassays that are more sensitive and specific should be used.

Rapid immune-chromatographic cartridge assays also are available but should not take the place of routine ova and parasite examination. Only molecular testing (e.g., polymerase chain reaction) can be used to identify the sub types of *Giardia*.

Illness & Symptoms

Giardiasis is the most frequently diagnosed intestinal parasitic disease in the United States and among travelers with chronic diarrhea. Signs and symptoms may vary and can last for 1 to 2 weeks or longer. In some cases, people infected with *Giardia* have no symptoms

Acute symptoms include:

- Diarrhea
- Gas
- Greasy stools that tend to float
- Stomach or abdominal cramps
- Upset stomach or nausea/vomiting
- Dehydration (loss of fluids)

Other, less common symptoms include itchy skin, hives, and swelling of the eye and joints. Sometimes, the symptoms of giardiasis might seem to resolve, only to come back again after several days or weeks. Giardiasis can cause weight loss and failure to absorb fat, lactose, vitamin A and vitamin B12

In children, severe giardiasis might delay physical and mental growth, slow development, and cause malnutrition

APPLIED ZOOLOGY AND LAB WORK
PATHOGENECITY

Giardia causes giardiasis which includes violent diarrhoea, excess gas, stomach cramps, nausea, blood & pus in stools resulting in dehydration. It also causes the villi of small intestine to atrophy & flatten resulting in malabsorption.

Sources of Infection & Risk Factors

General Epidemiology

Giardiasis is a diarrheal illness caused by the parasite *Giardia intestinalis* (also known as *Giardia lamblia* or *Giardia duodenalis*).

Giardiasis is a global disease. It infects nearly 2% of adults and 6% to 8% of children in developed countries worldwide. Nearly 33% of people in developing countries have had giardiasis. In the United States, *Giardia* infection is the most common intestinal parasitic disease affecting humans.

People become infected with *Giardia* by swallowing *Giardia* cysts (hard shells containing *Giardia*) found in contaminated food or water. Cysts are instantly infectious once they leave the host through feces (poop). An infected person might shed 1-10 billion cysts daily in their feces (poop) and this might last for several months. However, swallowing as few as 10 cysts might cause someone to become ill. *Giardia* may be passed from person-to-person or even from animal-to-person. Also, oral-anal contact during sex has been known to cause infection. Symptoms of giardiasis normally begin 1 to 3 weeks after a person has been infected.

Giardia infection rates have been known to go up in late summer. Between 2006-2008 in the United States, known cases of giardiasis were twice as high between June-October as they were between January-March.

Anyone may become infected with *Giardia*. However, those at greatest risk are

- Travelers to countries where giardiasis is common
- People in childcare settings
- Those who are in close contact with someone who has the disease
- People who swallow contaminated drinking water
- Backpackers or campers who drink untreated water from lakes or rivers
- People who have contact with animals who have the disease
- Men who have sex with men

Molecular Characterization

Giardia intestinalis (aka: *G. duodenalis*, *G. lamblia*) can be subdivided based on molecular analysis into what are known as different genetic assemblages (A,B,C,D,E,F, and G). Some

APPLIED ZOOLOGY AND LAB WORK

of these assemblages can be classified even further into subtypes like for example A-I, A-II, A-III, A-IV. Each assemblage is capable of infecting certain species, and some assemblages are more commonly seen than others:

Molecular Characterization	
Assemblages	Some Species Commonly Infected
A-I	Humans and animals (cats, dogs, livestock, deer, muskrats, beavers, voles, guinea pigs, ferrets)
A-II	Humans (more common than A-I)
A-III and A-IV	Exclusively animals
B	Humans and animals (livestock, chinchillas, beavers, marmosets, rodents)
C and D	Dogs, coyotes
E	Alpacas, cattle, goats, pigs, sheep
F	Cats

Prevention & Control

❖ Practice good hygiene.

- *Everywhere*
 - Wash hands with soap and clean, running water for at least 20 seconds; rub your hands together to make lather and be sure to scrub the backs of your hands, between your fingers, and under your nails.
 - Before, during, and after preparing food
 - Before eating food
 - Before and after caring for someone who is sick
 - Before and after treating a cut or wound
 - After using the toilet
 - After changing diapers or cleaning up a child who has used the toilet
 - After blowing your nose, coughing, or sneezing
 - After touching an animal or animal waste
 - After handling pet food or pet treats
 - After touching garbage
 - Help young children and other people you are caring for with handwashing as needed.

APPLIED ZOOLOGY AND LAB WORK

Thoroughly washing your hands after gardening can help prevent exposure to parasitic diseases.

- *At childcare facilities*
 - To reduce the risk of spreading the disease, children with diarrhea should be removed from child care settings until the diarrhea has stopped.
- *At recreational water venues (for example, pools, beaches, fountains)*
 - Protect others by not swimming if you have diarrhea (this is most important for children in diapers).
 - If diagnosed with giardiasis, do not swim for at least 1 week after diarrhea stops.
 - Shower before entering the water.
 - Wash children thoroughly (especially their bottoms) with soap and water after they use the bathroom or after their diapers are changed and before they enter the water.
 - Take children on frequent bathroom breaks and check their diapers often.
 - Change diapers in the bathroom, not by the water.
- *Around animals*
 - Minimize contact with the feces (poop) of all animals, especially young animals.
 - When cleaning up animal feces (poop), wear disposable gloves and always wash hands when finished.
 - Wash hands after any contact with animals or their living areas.
- *Outside*
 - Wash hands after gardening, even if wearing gloves.

❖ **Avoid water (drinking and recreational) that may be contaminated.**

- Do not swallow water while swimming in pools, hot tubs, interactive fountains, lakes, rivers, springs, ponds, streams or the ocean.
- Do not drink untreated water from lakes, rivers, springs, ponds, streams, or shallow wells.
- Do not drink poorly treated water or ice made from water during community outbreaks caused by contaminated drinking water.
- Do not use or drink poorly treated water or use ice when traveling in countries where the water supply might be unsafe.
- If the safety of drinking water is in doubt (for example, during or after an outbreak, in a place with poor sanitation or lack of water treatment systems), do one of the following:
 - Drink bottled water.
 - Disinfect tap water by heating it to a rolling boil for 1 minute.

APPLIED ZOOLOGY AND LAB WORK

- Use a filter that has been tested and rated by National Safety Foundation (NSF) Standard 53 or NSF Standard 58 for cyst and oocyst reduction; filtered tap water will need additional treatment to kill or weaken bacteria and viruses.

❖ **Avoid eating food that may be contaminated.**

- Use safe, uncontaminated water to wash all food that is to be eaten raw.
- After washing vegetables and fruit in safe, uncontaminated water, peel them if you plan to eat them raw.
- Avoid eating raw or uncooked foods when traveling in countries with poor food and water treatment.

❖ **Prevent contact and contamination with feces (poop) during sex.**

- Use a barrier during oral-anal sex.
- Wash hands right after handling a condom used during anal sex and after touching the anus or rectal area.

❖ **Clean up after ill pets and people.**

Giardia is hard to completely eliminate from the environment, but you can decrease the risk of human infection or of your dog's or cat's reinfection if it has been ill. The risk of acquiring *Giardia* infection from your dog or cat is small, but there are some steps you can take to minimize your exposure.

Clean and disinfect your home in this way:

- **Hard surfaces** (for example: cement and tile floors, pet crates, tables, trash cans, etc.)
 - **Cleaning**
 - Wear gloves.
 - Remove feces and discard in a plastic bag.
 - Clean and scrub surfaces using soap. Rinse surface thoroughly until no obvious visible contamination is present.
 - **Disinfection**
 - Wear gloves.
 - Disinfect according to manufacturer guidelines using **one** of the following:
 - Quaternary ammonium compound products (QATS) ¹, which are found in some household cleaning products; the active ingredient may be listed as alkyl dimethyl ammonium chloride.
 - Bleach mixed with water (3/4 cup of bleach to 1 gallon of water) ².

APPLIED ZOOLOGY AND LAB WORK

- Follow product instructions, ensuring the product stays in contact with the surface for the recommended amount of time.
 - Rinse with clean water.
- **Carpet / Upholstered Furniture**
 - **Cleaning**
 - Wear gloves.
 - If feces are on a carpet or upholstered furniture, remove them with absorbent material (for example, double layered paper towels).
 - Place and discard the feces in a plastic bag.
 - Clean the contaminated area with regular detergent or carpet cleaning agent.
 - Allow carpet or upholstered furniture to fully dry.
 - **Disinfection**
 - Wear gloves.
 - Steam cleans the area at 158°F for 5 minutes or 212°F for 1 minute.
 - QATS are found in some carpet cleaning products and can also be used after cleaning to disinfect. Read the product labels for specifications, and follow all instructions.
 - **Other items (toys, clothing, pet bed, etc.)**
 - Household items should be cleaned and disinfected daily while a dog or cat is being treated for *Giardia* infection.
 - **Dishwasher**
 - Dishwasher-safe toys and water and food bowls can be disinfected in a dishwasher that has a dry cycle or a final rinse that exceeds **one** of the following:
 - 113°F for 20 minutes
 - 122°F for 5 minutes
 - 162°F for 1 minute
 - If a dishwasher is not available, submerge dishwasher-safe items in boiling water for at least 1 minute (at elevations above 6,500 feet, boil for 3 minutes).
 - **Washer and Dryer**
 - Clothing, some pet items (for example, bedding and cloth toys) and linens (sheets and towels) can be washed in the washing machine and then heat-dried on the highest heat setting for 30 minutes.
 - If a clothes dryer is not available, allow clothes to thoroughly air dry under direct sunlight.

Treatment

APPLIED ZOOLOGY AND LAB WORK

- *Giardia* trophozoites under scanning electron microscope. Credit: Waterborne Disease Prevention Branch, CDC
- Several drugs can be used to treat *Giardia* infection. Effective treatments include metronidazole, tinidazole, and nitazoxanide ¹. Alternatives to these medications include paromomycin, quinacrine, and furazolidone. Some of these drugs may not be routinely available in the United States.
- Different factors may shape how effective a drug regimen will be, including medical history, nutritional status, and condition of the immune system. Therefore, it is important to discuss treatment options with a healthcare provider.

9.8 ASCARIS

Systematic Position

Phylum- Nematoda

Class- Phasmodia

Order- Ascaroidea

Suborder- Ascarinae

Family- Ascaridae

Genus- *Ascaris*

Species- *lumbricoides*

General characters

- It is an endoparasite of man found in small intestine.
- It is cosmopolitan in distribution.
- It is commonly called as round worm.
- It is monogenetic nematode.
- Body is un-segmented, elongated, cylindrical in shape, white pinkish in colour tapering at both ends.
- Female ascaris is larger than male ascaris.
- It is dioecious in nature.
- It respire anaerobically i.e. in the body of host where it lives, the amount of oxygen is relatively less inside intestine to which it adapts by carrying anerobic respiration.
- Locomotory structures are absent as they need not move in search of food.

APPLIED ZOOLOGY AND LAB WORK

- To protect from the harmful effects of digestive enzymes of the host, body is covered by tough protective cuticle.
- Digestive system is not well developed as it feeds upon partially digested food of host which is also an adaptation.
- Excretory system is primitive with absence of flame cells.
- Nervous system is primitive.
- To remain at the specific site of infection they attach to the surrounding tissues provided with adhesive structures like hooks.
- Low metabolic rate.
- The reproductive potential is very high by laying 2,00,000 eggs day which ensures the contamination of new host.
- Eggs are enclosed inside a protective covering called cyst to thrive in harsh environmental conditions.
- Fertilization is external.

An estimated 807-1,221 million people in the world are infected with *Ascaris lumbricoides* (sometimes called just "*Ascaris*"). *Ascaris*, hookworm, and whipworm are known as soil-transmitted helminths (parasitic worms). Together, they account for a major burden of disease worldwide. Ascariasis is now uncommon in the United States.

Ascaris lives in the intestine and *Ascaris* eggs are passed in the feces of infected persons. If the infected person defecates outside (near bushes, in a garden, or field) or if the feces of an infected person are used as fertilizer, eggs are deposited on soil. They can then mature into a form that is infective. Ascariasis is caused by ingesting eggs. This can happen when hands or fingers that have contaminated dirt on them are put in the mouth or by consuming vegetables or fruits that have not been carefully cooked, washed or peeled.

People infected with *Ascaris* often show no symptoms. If symptoms do occur they can be light and include abdominal discomfort. Heavy infections can cause intestinal blockage and impair growth in children. Other symptoms such as cough are due to migration of the worms through the body. Ascariasis is treatable with medication prescribed by your health care provider.

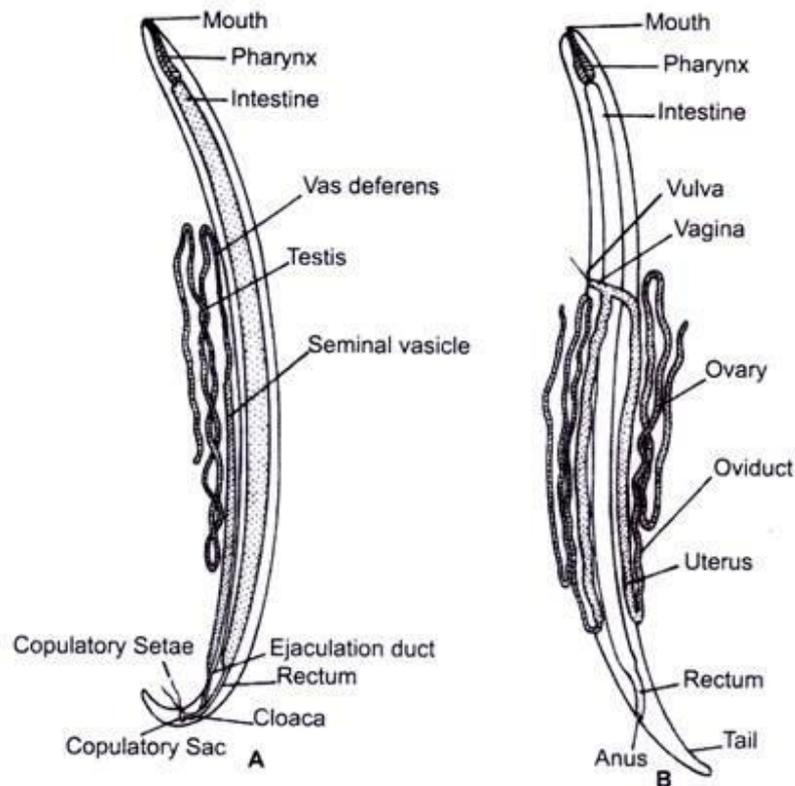

Fig 9.9 (A) Adult Male (B) Adult Female

LIFE –CYCLE

The egg containing larva when ingested with contaminated raw vegetables causes ascariasis. Ingested eggs hatch in the duodenum. The larvae penetrate the intestinal wall and circulate in the blood. From the heart they migrate to the lungs, ascend to the trachea, descend to the oesophagus and finally reach the small intestine to become adult. The female pass immature eggs which pass to the soil and mature in 2 weeks.

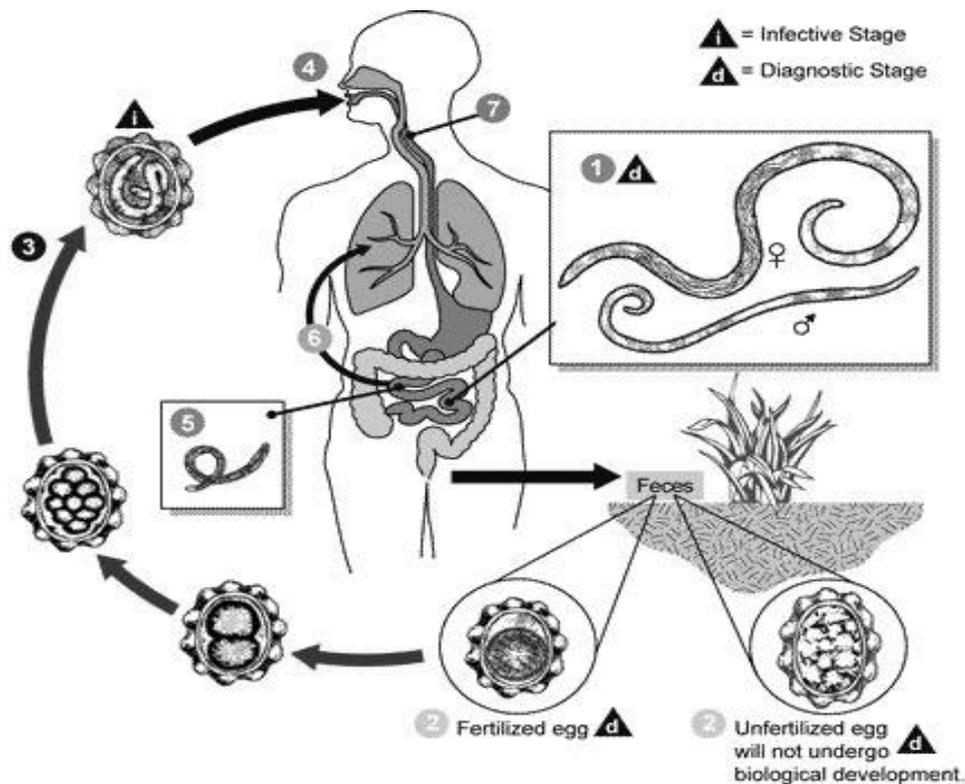

Fig. 9.10 Life Cycle

Adult worms live in the lumen of the small intestine. A female may produce approximately 200,000 eggs per day, which are passed with the feces. Unfertilized eggs may be ingested but are not infective. Fertile eggs embryonate and become infective after 18 days to several weeks, depending on the environmental conditions (optimum: moist, warm, shaded soil). After infective eggs are swallowed, the larvae hatch, invade the intestinal mucosa, and are carried via the portal, then systemic circulation to the lungs. The larvae mature further in the lungs (10 to 14 days), penetrate the alveolar walls, ascend the bronchial tree to the throat, and are swallowed. Upon reaching the small intestine, they develop into adult worms. Between 2 and 3 months are required from ingestion of the infective eggs to oviposition by the adult female. Adult worms can live 1 to 2 years.

PATHOGENECITY

Ascaris lumbricoides is the largest nematode (roundworm) parasitizing the human intestine. (Adult females: 20 to 35 cm; adult male: 15 to 30 cm.)

APPLIED ZOOLOGY AND LAB WORK

It causes ascariasis which results in inflammation of alveoli tissue, injuries to vital organs while Adult worms in the intestine cause abdominal pain and may cause intestinal obstruction especially in children. Larvae in the lungs may cause inflammation of the pneumonia-like symptoms.

People infected with *Ascaris* often show no symptoms. If symptoms do occur they can be light and include abdominal discomfort. Heavy infections can cause intestinal blockage and impair growth in children. Other symptoms such as cough are due to migration of the worms through the body. Ascariasis is treatable with medication prescribed by your health care provider.

Diagnosis

The standard method for diagnosing ascariasis is by identifying *Ascaris* eggs in a stool sample using a microscope. Because eggs may be difficult to find in light infections, a concentration procedure is recommended.

Treatment

Anthelmintic medications (drugs that rid the body of parasitic worms), such as albendazole and mebendazole, are the drugs of choice for treatment of *Ascaris* infections. Infections are generally treated for 1-3 days. The drugs are effective and appear to have few side effects.

The best way to prevent ascariasis is to always:

- Avoid ingesting soil that may be contaminated with human feces, including where human fecal matter ("night soil") or wastewater is used to fertilize crops.
- Wash your hands with soap and warm water before handling food.
- Teach children the importance of washing hands to prevent infection.
- Wash, peel, or cook all raw vegetables and fruits before eating, particularly those that have been grown in soil that has been fertilized with manure.

Transmission of infection to others can be prevented by

- Not defecating outdoors.
- Effective sewage disposal systems.

9.9 ANCYLOSTOMA

Systematic Position

Phylum- Nematoda

Class- Phasmidia

Order- Strongyloidea

Family- Ancylostomidae

Genus- *Ancylostoma*

Species- *dudoenale*

Ancylostoma Duodenale was discovered by an Italian physician, Angelo Ducini Looss in 1898. It is found in the small intestine of millions of people chiefly in Europe, Africa, India, China, Japan, Srilanka and Pacific Islands.

General characters

- Generally known as hook worm.
- It is a monogenetic parasite of humans.
- Found in tropical & sub-tropical, temperate regions of the world.
- It is greyish white in colour.
- Body is ventrally curved.
- Females are larger than males.
- Presence of cup shaped cavity armed with cutting plates bearing teeth/lancets for adhesion to the host.
- Secretes anti-coagulant.
- Respiration anaerobic as live inside the intestine where supply of oxygen is less.
- Body covered with cuticle to protect from hosts digestive enzymes.
- Production of enormous number of eggs i.e. high fertility rate.
- Minute size & resistant nature of eggs helps in their wide dispersal.
- Sexes are separate.

The hookworm, *Ancylostoma duodenale*, is a nematode that mainly parasitizes humans. However, it can also be found in a range of paratenic hosts, including dogs, cats, pigs, and

even coyotes. These tiny, s-shaped worms only grow to be roughly 8-13 mm in length. Although it is very small, it still contains a very vicious “bite”.

Each hookworm contains two very powerful ventral teeth, along with small pairs of teeth located deeper in its capsule to help it bite and attach itself to its victims. Once inside, the parasite will hook itself onto the intestines and continually drain blood from its host, up to 1 mL blood per individual per day. Sexual dimorphism occurs. The male worm is 8 to 11 mm x 0.4 mm in size. The posterior end of the body forms a bursa made of three lobes, out of which one is dorsal and two are lateral. A pair of long spicules passes from the genital canal to the outside through cloaca. A gubernaculum is also used during copulation to help guide the spicules.

The female averages 10 to 13 mm x 0.6 mm in size. The posterior end of the body tapers to a rather blunt point. The vulva is located at a point about two-thirds the length of the body from the anterior end. Eggs are ovoidal, thin-shelled and measure 56 to 60 um x 34 – 40 um.

A. duodenale infects humans mainly through direct contact, which usually occurs through the foot. However, it can also be transmitted through the consumption of under-cooked meats such as lamb, beef, and pork. The parasites are released back into the soil through human feces.

Infants are more vulnerable than adults, and infections in children can lead to permanent growth deficiencies.

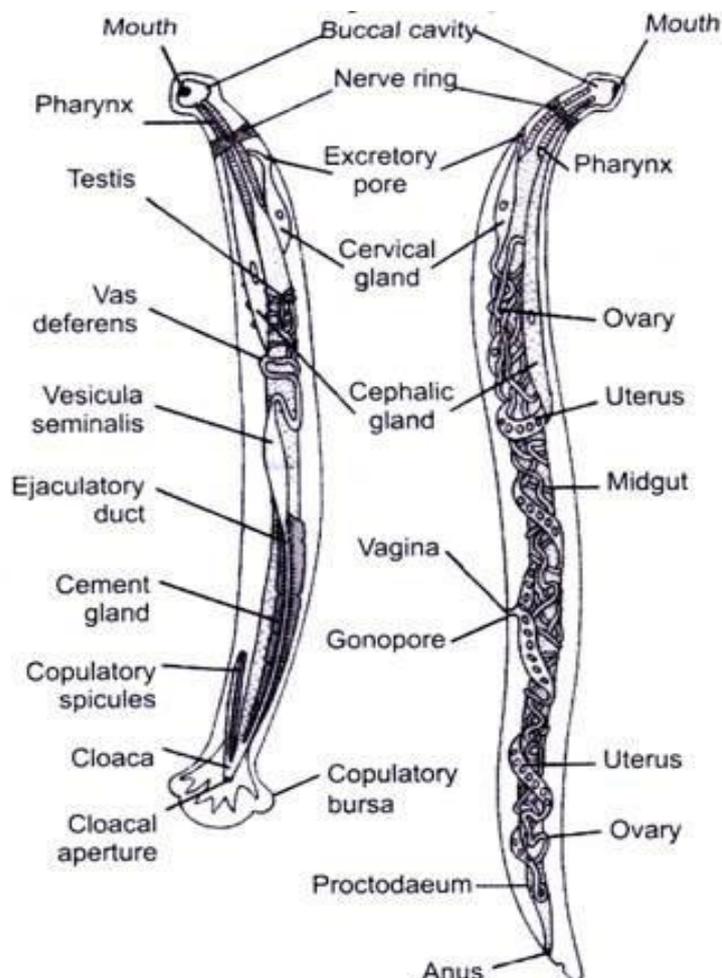

Fig.9.11 Male and Female *A. duodenale*

LIFE-CYCLE

It is monogenetic in nature & involve only one host in its life cycle i.e. man. Adult male and female worms live in the small intestine. The female lays eggs, which contain immature embryo in the 4 cell stage. When the eggs pass in the stool to the soil and under favourable conditions of temperature, moisture and oxygen, they hatch into larvae, which molt twice and become infective. When the filariform larvae penetrate the skin, they circulate in the blood, reach the lungs, ascend to the trachea, descend to oesophagus to reach the small intestine and become adults, where they get attached to mucous lining & feed on blood of host. The adult copulate to produce eggs which are fertilized externally. Fertilized eggs are passed out with host faeces which under favourable environmental conditions hatch into rhabditi form larva & wait to infect a new host through skin contact.

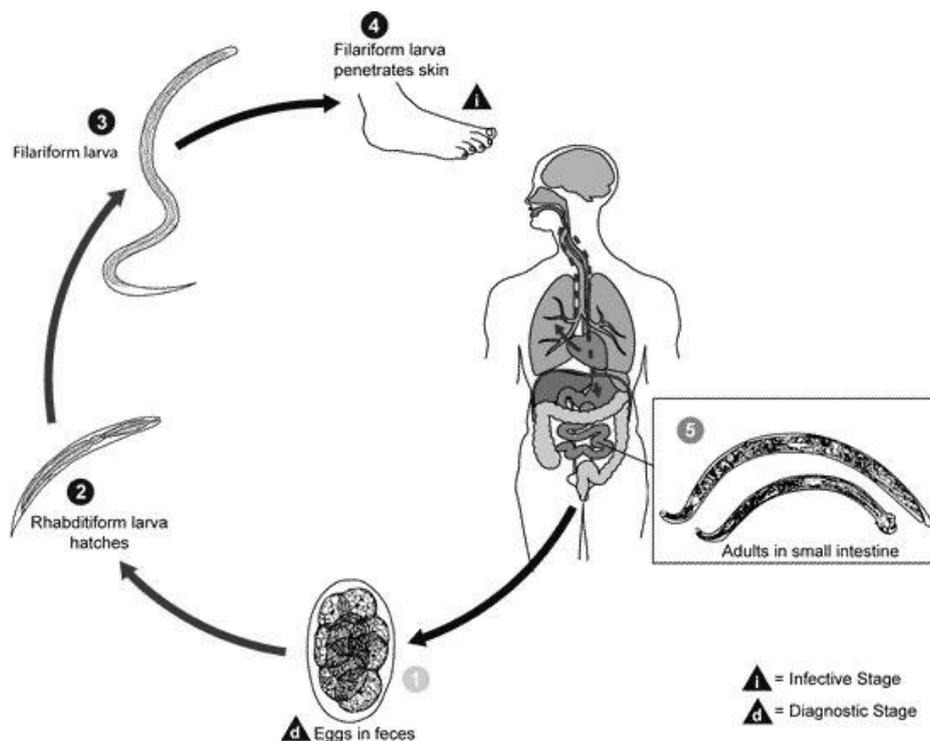

Fig 9.12 Life cycle

Eggs are passed in the stool, and under favorable conditions (moisture, warmth, shade), larvae hatch in 1 to 2 days. The released rhabditiform larvae grow in the feces and/or the soil, and after 5 to 10 days (and two molts) they become filariform (third-stage) larvae that are infective. These infective larvae can survive 3 to 4 weeks in favorable environmental conditions. On contact with the human host, the larvae penetrate the skin and are carried through the blood vessels to the heart and then to the lungs. They penetrate into the pulmonary alveoli, ascend the bronchial tree to the pharynx, and are swallowed. The larvae reach the small intestine, where they reside and mature into adults. Adult worms live in the lumen of the small intestine, where they attach to the intestinal wall with resultant blood loss by the host. Most adult worms are eliminated in 1 to 2 years, but the longevity may reach several years.

Some *A. duodenale* larvae, following penetration of the host skin, can become dormant (in the intestine or muscle). In addition, infection by *A. duodenale* may probably also occur by the oral and transmammary route. *N. americanus*, however, requires a transpulmonary migration phase.

PATHOGENECITY

Ancylostoma causes ancylostomiasis in which itching of skin, severe inflammation, diarrhoea, constipation with bloody stools. Adult worms in the intestine feed on blood causing iron deficiency anaemia. The larvae cause inflammation of the lungs. In severe conditions mental retardation in children is caused.

Anemia of iron deficiency is the principal host reaction to the intestinal infection by adult worms. Other symptoms are fever, abdominal pain, diarrhoea, food fermentation, constipation, myocarditis, eosinophilia, loss of health and collapse. Children are more susceptible than adults. Mental and physical growth is retarded in children and growing youth.

To check the epigastric pain, the patient may start eating even dirt, so called “dirt eaters”. If the infection is not controlled, it may lead to fatty degeneration of heart, liver and kidneys, ending in the death of the patient.

Prevention and Control

Many drugs are available to treat ancylostomiasis. The most commonly used drug is tetrachloroethylene or blephenium hydroxynaphthoate, because of its high efficiency and low toxicity. Other antihelmintic drugs used are Hexylresorcinol, thymol, oil of chenopodium, dithiazanine iodide, piperazine salt, pyrvinium pamoate. Thioabendazole can be given, but only under strict supervision of a physician. Food is usually supplemented by iron to compensate haemoglobin deficiency.

Control:

1. Proper sewage disposal in affected areas.
2. Keep soil free from contamination of larvae.
3. Educate the people in endemic area concerning the source of infection.
4. Wear shoes regularly.

9.10 ENTEROBIUS

Systematic Position

Phylum- Nematoda

Class- Secernentea

Subclass- Spiruria

Order- Oxyurida

Family- Oxyuridae

Genus- *Enterobius*

Species- *vermicularis*

General characters

- Commonly called as Pin worm.
- It is a monogenetic parasitic nematode.
- It is white in color.
- Females are larger in size than males.
- They give thread like appearance.
- Found in upper part of the colon.
- Sexual dimorphism occurs.
- Tail of female is long & pointed where as that of male is blunt & curved.
- Male is monarchic while female is didelphic i.e. possessing two wombs.

Pinworm infection is caused by a small, thin, white roundworm called *Enterobius vermicularis*. Although pinworm infection can affect all people, it most commonly occurs among children, institutionalized persons, and household members of persons with pinworm infection.

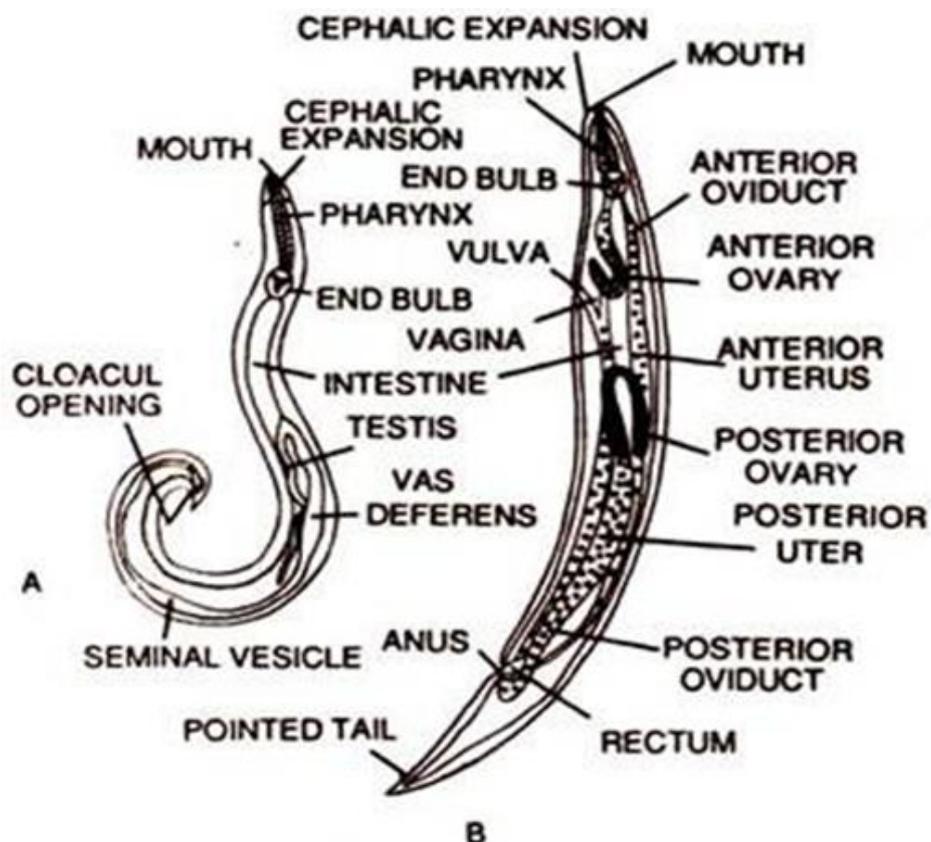

Fig 9.13 *Enterobius vermicularis*

LIFE-CYCLE

As it is monogenetic in nature life cycle is simple with man being the only host. Adult worm lives in the large intestine. After fertilization, the male dies and the Female moves out through at night to the anus to glue its eggs on the peri-anal skin. The eggs are plano-convex and contains larva. When the eggs are swallowed, they hatch in the small intestine and the larvae migrate to the large intestine to become adult.

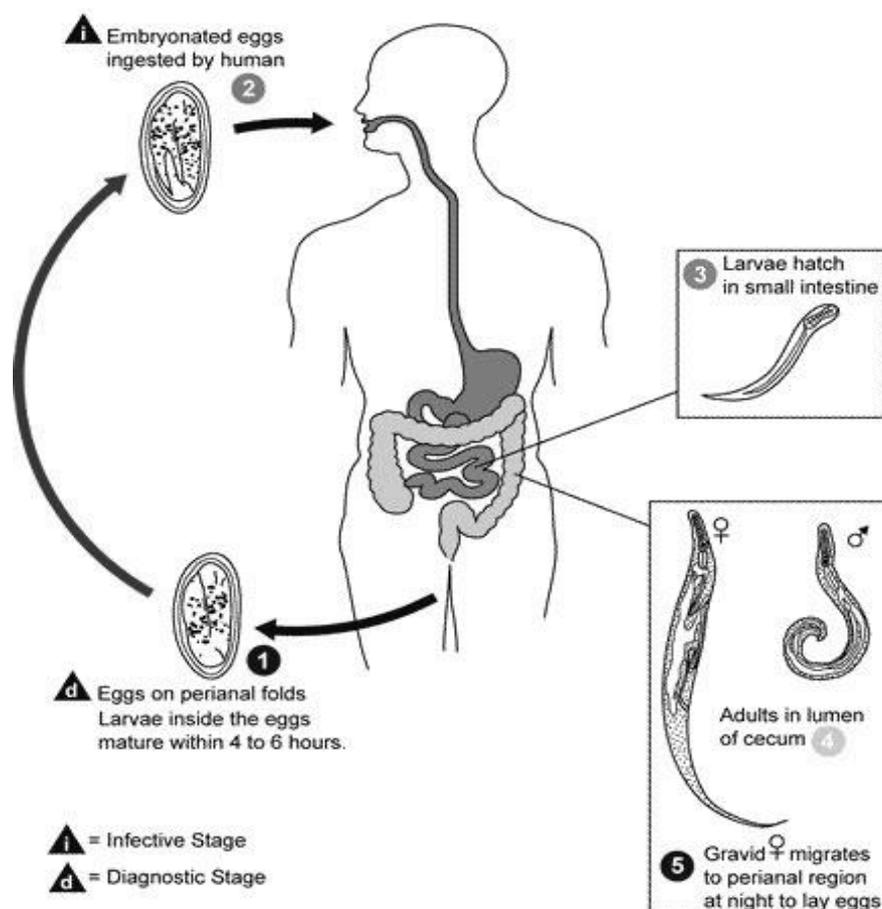

Fig.9.14 Life Cycle

Eggs are deposited on perianal folds. Self-infection occurs by transferring infective eggs to the mouth with hands that have scratched the perianal area. Person-to-person transmission can also occur through handling of contaminated clothes or bed linens. Enterobiasis may also be acquired through surfaces in the environment that are contaminated with pinworm eggs (e.g. , curtains, carpeting). Some small number of eggs may become airborne and inhaled. These would be swallowed and follow the same development as ingested eggs. Following ingestion of infective eggs, the larvae hatch in the small intestine and the adults establish themselves in the colon. The time interval from ingestion of infective eggs to oviposition by the adult females is about one month. The life span of the adults is about two months. Gravid females migrate nocturnally outside the anus and oviposit while crawling on the skin of the perianal area. The larvae contained inside the eggs develop (the eggs become infective) in 4 to 6 hours under optimal conditions. Retroinfection, or the migration of newly hatched larvae from the anal skin back into the rectum, may occur but the frequency with which this happens is unknown.

PATHOGENECITY

Pinworm infections are more common within families with school-aged children, in primary caregivers of infected children, and in institutionalized children.

A person is infected with pinworms by ingesting pinworm eggs either directly or indirectly. These eggs are deposited around the anus by the worm and can be carried to common surfaces such as hands, toys, bedding, clothing, and toilet seats. By putting anyone's contaminated hands (including one's own) around the mouth area or putting one's mouth on common contaminated surfaces, a person can ingest pinworm eggs and become infected with the pinworm parasite. Since pinworm eggs are so small, it is possible to ingest them while breathing.

Once someone has ingested pinworm eggs, there is an incubation period of 1 to 2 months or longer for the adult gravid female to mature in the small intestine. Once mature, the adult female worm migrates to the colon and lays eggs around the anus at night, when many of their hosts are asleep. People who are infected with pinworm can transfer the parasite to others for as long as there is a female pinworm depositing eggs on the perianal skin. A person can also re-infect themselves, or be re-infected by eggs from another person.

The migration of the worms causes allergic reactions around the anus and during night it causes nocturnal itching and enuresis. The worms obstruct the appendix causing appendicitis. Parasite also causes loss of appetite, insomnia, hysteria, restlessness and inflammation to the patient.

The most common clinical manifestation of a pinworm infection is an itchy anal region. When the infection is heavy, there can be a secondary bacterial infection due to the irritation and scratching of the anal area. Often the patient will complain of teeth grinding, and insomnia due to disturbed sleep, or even abdominal pain or appendicitis. Infection of the female genital tract has been well reported.

Diagnosis & Treatment

A person infected with pinworm is often asymptomatic, but itching around the anus is a common symptom. Diagnosis of pinworm can be reached from three simple techniques. The first option is to look for the worms in the perianal region 2 to 3 hours after the infected person is asleep. The second option is to touch the perianal skin with transparent tape to

APPLIED ZOOLOGY AND LAB WORK

collect possible pinworm eggs around the anus first thing in the morning. If a person is infected, the eggs on the tape will be visible under a microscope. The tape method should be conducted on 3 consecutive morning's right after the infected person wakes up and before he/she does any washing. Since anal itching is a common symptom of pinworm, the third option for diagnosis is analyzing samples from under fingernails under a microscope. An infected person who has scratched the anal area may have picked up some pinworm eggs under the nails that could be used for diagnosis.

Since pinworm eggs and worms are often sparse in stool, examining stool samples is not recommended. Serologic tests are not available for diagnosing pinworm infections.

The medications used for the treatment of pinworm are mebendazole, pyrantel pamoate, or albendazole. Any of these drugs are given in one dose initially, and then another single dose of the same drug two weeks later. Pyrantel pamoate is available without prescription. The medication does not reliably kill pinworm eggs. Therefore, the second dose is to prevent re-infection by adult worms that hatch from any eggs not killed by the first treatment. Health practitioners and parents should weigh the health risks and benefits of these drugs for patients under 2 years of age.

Repeated infections should be treated by the same method as the first infection. In households where more than one member is infected or where repeated, symptomatic infections occur, it is recommended that all household members be treated at the same time. In institutions, mass and simultaneous treatment, repeated in 2 weeks, can be effective.

Prevention and Control

Washing your hands with soap and warm water after using the toilet, changing diapers, and before handling food is the most successful way to prevent pinworm infection. In order to stop the spread of pinworm and possible re-infection, people who are infected should bathe every morning to help remove a large amount of the eggs on the skin. Showering is a better method than taking a bath, because showering avoids potentially contaminating the bath water with pinworm eggs. Infected people should not co-bathe with others during their time of infection.

Also, infected people should comply with good hygiene practices such as washing their hands with soap and warm water after using the toilet, changing diapers, and before handling food.

APPLIED ZOOLOGY AND LAB WORK

They should also cut fingernails regularly, and avoid biting the nails and scratching around the anus. Frequent changing of underclothes and bed linens first thing in the morning is a great way to prevent possible transmission of eggs in the environment and risk of reinfection. These items should not be shaken and carefully placed into a washer and laundered in hot water followed by a hot dryer to kill any eggs that may be there.

In institutions, day care centers, and schools, control of pinworm can be difficult, but mass drug administration during an outbreak can be successful. Teach children the importance of washing hands to prevent infection.

9.11 WUCHEREIA

Systematic Position

Phylum- Nematoda

Class- Phasmidia

Order- Filarioidea

Family- Filariidea

Genus- *Wucheria*

Species- *bancrofti*

General characters

- It is a digenetic nematode parasite.
- It is confined to tropical & sub tropical countries.
- It is an endoparasite of human blood & lymphatic system.
- Its primary host is man where as secondary host is invertebrate i.e. mosquito.
- It is filliform & cylindrical in shape with terminal blunt ends.
- These are creamy white in colour.
- Sexes are separate.
- Females are longer than males.
- Its larvae are termed as microfilaria which shows diurnal rhythm.
- Sheath covering on microfilaria for protection from host immune system.
- Adhesive structures are present to remain attached to the host.
- Polyembryony occurs i.e. presence of many larval stages.

APPLIED ZOOLOGY AND LAB WORK

There are three different filarial species that can cause lymphatic filariasis in humans. Most of the infections worldwide are caused by *Wuchereria bancrofti*. In Asia, the disease can also be caused by *Brugia malayi* and *Brugia timori*.

Lymphatic filariasis, considered globally as a neglected tropical disease, is a parasitic disease caused by microscopic, thread-like worms. The adult worms only live in the human lymph system. The lymph system maintains the body's fluid balance and fights infections. Lymphatic filariasis is spread from person to person by mosquitoes. The adult worm lives in the human lymph vessels, mates, and produces millions of microscopic worms, also known as microfilariae. Microfilariae circulate in the person's blood and infect the mosquito when it bites a person who is infected. Microfilariae grow and develop in the mosquito. When the mosquito bites another person, the larval worms pass from the mosquito into the human skin, and travel to the lymph vessels. They grow into adult worms, a process that takes 6 months or more. An adult worm lives for about 5–7 years. The adult worms mate and release millions of microfilariae into the blood. People with microfilariae in their blood can serve as a source of infection to others.

People with the disease can suffer from lymphedema and elephantiasis and in men, swelling of the scrotum, called hydrocele. Lymphatic filariasis is a leading cause of permanent disability worldwide. Communities frequently shun and reject women and men disfigured by the disease. Affected people frequently are unable to work because of their disability, and this harms their families and their communities.

Programs to eliminate lymphatic filariasis are under way in more than 50 countries. These programs are reducing transmission of the filarial parasites and decreasing the risk of infection for people living in or visiting these communities.

The infection spreads from person to person by mosquito bites.

A wide range of mosquitoes can transmit the parasite, depending on the geographic area. In Africa, the most common vector is *Anopheles* and in the Americas, it is *Culex quinquefasciatus*. *Aedes* and *Mansonia* can transmit the infection in the Pacific and in Asia.

Many mosquito bites over several months to years are needed to get lymphatic filariasis. People living for a long time in tropical or sub-tropical areas where the disease is common are at the greatest risk for infection. Short-term tourists have a very low risk.

Lymphatic filariasis affects over 120 million people in 73 countries throughout the tropics and sub-tropics of Asia, Africa, the Western Pacific, and parts of the Caribbean and South America.

APPLIED ZOOLOGY AND LAB WORK

Only four countries are currently known to be endemic: Haiti, the Dominican Republic, Guyana and Brazil.

In the United States, Charleston, South Carolina, was the last known place with lymphatic filariasis. The infection disappeared early in the 20th century. Currently, you cannot get infected in the U.S.

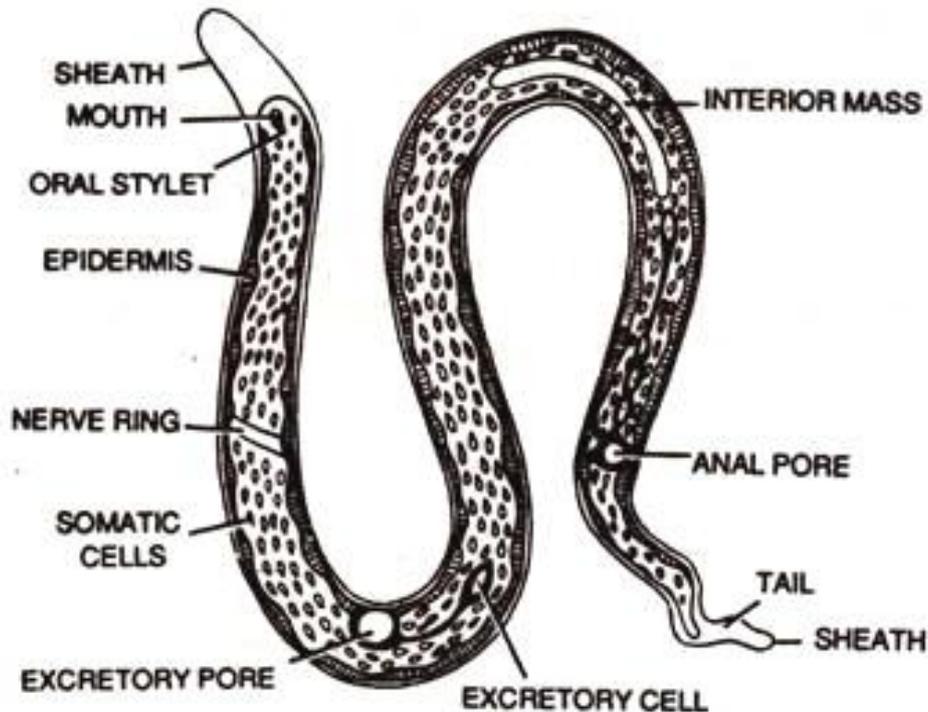

Fig 9.15 *Wucheria bancrofti*

LIFE-CYCLE

The filariform larvae are introduced through the skin by the bite of the arthropod intermediate host. The larvae invade the lymphatics, usually the lower limb, where they develop into adult worms. The microfilariae are liberated into the blood stream. They remain in the pulmonary circulation during day, emerging into the peripheral circulation only during night, to coincide with the biting habit of the vector.

The parasite when sucked up by vector moves into its stomach where they metamorphosis from long slender form to plump sausage shaped organism ready to cause infection to a new host when bitten by vector. Infective larvae are transmitted by infected biting mosquitoes during a blood meal. The larvae migrate to lymphatic vessels and lymph nodes, where they develop into microfilariae-producing adults. The adults dwell in lymphatic vessels and lymph nodes where they can live for several years. The female worms produce

microfilariae which circulate in the blood. The microfilariae infect biting mosquitoes. Inside the mosquito, the microfilariae develop in 1 to 2 weeks into infective filariform (third-stage) larvae. During a subsequent blood meal by the mosquito, the larvae infect the human host. They migrate to the lymphatic vessels and lymph nodes of the human host, where they develop into adults.

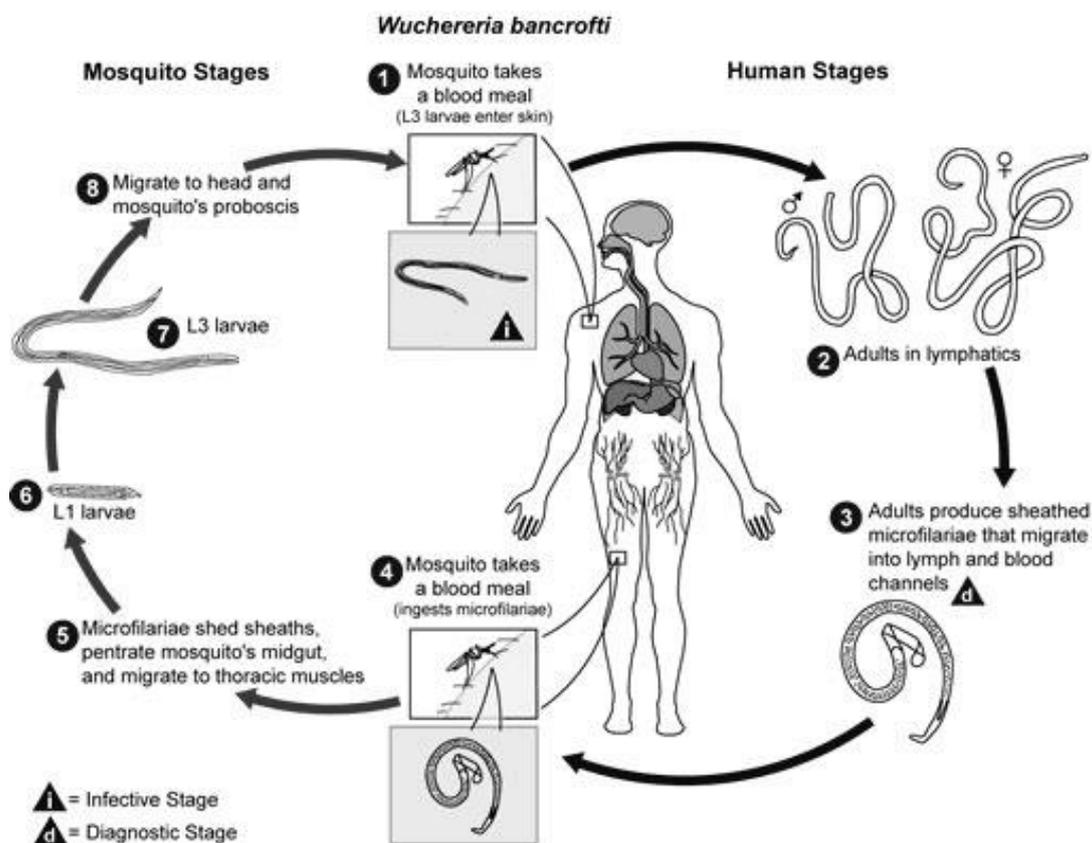

Fig.9.16 Life Cycle

During a blood meal, an infected mosquito introduces third-stage filarial larvae onto the skin of the human host, where they penetrate into the bite wound. They develop in adults that commonly reside in the lymphatics. The female worms measure 80 to 100 mm in length and 0.24 to 0.30 mm in diameter, while the males measure about 40 mm by .1 mm. Adults produce microfilariae measuring 244 to 296 μm by 7.5 to 10 μm , which are sheathed and have nocturnal periodicity, except the South Pacific microfilariae which have the absence of marked periodicity. The microfilariae migrate into lymph and blood channels moving actively through lymph and blood. A mosquito ingests the microfilariae during a blood meal.

APPLIED ZOOLOGY AND LAB WORK

After ingestion, the microfilariae lose their sheaths and some of them work their way through the wall of the proventriculus and cardiac portion of the mosquito's midgut and reach the thoracic muscles. There the microfilariae develop into first-stage larvae and subsequently into third-stage infective larvae. The third-stage infective larvae migrate through the hemocoel to the mosquito's proboscis and can infect another human when the mosquito takes a blood meal.

Different species of the following genera of mosquitoes are vectors of *W. bancrofti* filariasis depending on geographical distribution. Among them are: *Culex* (*C. annulirostris*, *C. bitaeniorhynchus*, *C. quinquefasciatus*, and *C. pipiens*); *Anopheles* (*A. arabinensis*, *A. bancroftii*, *A. farauti*, *A. funestus*, *A. gambiae*, *A. koliensis*, *A. melas*, *A. merus*, *A. punctulatus* and *A. wellcomei*); *Aedes* (*A. aegypti*, *A. aquasalis*, *A. bellator*, *A. cooki*, *A. darlingi*, *A. kochi*, *A. polynesiensis*, *A. pseudoscutellaris*, *A. rotumae*, *A. scapularis*, and *A. vigilax*); *Mansonia* (*M. pseudotitillans*, *M. uniformis*); *Coquillettidia* (*C. juxtamansonia*).

PATHOGENECITY

Lymphatic filariasis is caused by nematodes (roundworms) that inhabit the lymphatic vessels and lymph nodes of a human host. *Wuchereria bancrofti*, *Brugia malayi* and *Brugia timori* cause lymphatic filariasis.

Wuchereria causes disease termed as Filariasis. The adult worm obstructs the flow of lymph in the lymph nodes and the lymphatic vessels draining the lower limbs and the external genitalia become swollen. The skin becomes thick and fissured. The disease is also called elephantiasis in which the body parts grow in enormous size. The major symptoms include lymphangitis, lymphedema, fever, headache, myalgia, hydrocele and chyluria.

Although the parasite damages the lymph system, most infected people have no symptoms and will never develop clinical symptoms. These people do not know they have lymphatic filariasis unless tested. A small percentage of persons will develop lymphedema. This is caused by fluid collection because of improper functioning of the lymph system resulting in swelling. This mostly affects the legs, but can also occur in the arms, breasts, and genitalia. Most people develop these symptoms years after being infected.

The swelling and the decreased function of the lymph system make it difficult for the body to fight germs and infections. These people will have more bacterial infections in the skin and lymph system. This causes hardening and thickening of the skin, which is called elephantiasis. Many of these bacterial infections can be prevented with appropriate skin hygiene and exercise.

Men can develop hydrocele or swelling of the scrotum due to infection with one of the parasites that causes LF specifically *W. bancrofti*.

Filarial infection can also cause tropical pulmonary eosinophilia syndrome, although this syndrome is typically found in persons living with the disease in Asia. Symptoms of tropical pulmonary eosinophilia syndrome include cough, shortness of breath, and wheezing. The eosinophilia is often accompanied by high levels of IgE (Immunoglobulin E) and antifilarial antibodies.

Diagnosis and Treatment

The standard method for diagnosing active infection is the identification of microfilariae in a blood smear by microscopic examination. The microfilariae that cause lymphatic filariasis circulate in the blood at night (called nocturnal periodicity). Blood collection should be done at night to coincide with the appearance of the microfilariae, and a thick smear should be made and stained with Giemsa or hematoxylin and eosin. For increased sensitivity, concentration techniques can be used.

Serologic techniques provide an alternative to microscopic detection of microfilariae for the diagnosis of lymphatic filariasis. Patients with active filarial infection typically have elevated levels of antifilarial IgG4 in the blood and these can be detected using routine assays.

Because lymphedema may develop many years after infection, lab tests are most likely to be negative with these patients.

Patients currently infected with the parasite

Diethylcarbamazine (DEC) is the drug of choice in the United States. The drug kills the microfilaria and some of the adult worms. DEC has been used world-wide for more than 50 years. Because this infection is rare in the U.S., the drug is no longer approved by the Food and Drug Administration (FDA) and cannot be sold in the U.S. Physicians can obtain the medication from CDC after confirmed positive lab results. CDC gives the physicians the choice between 1 or 12-day treatment of DEC (6 mg/kg/day). One day treatment is generally as effective as the 12-day regimen. DEC is generally well tolerated. Side effects are in general limited and depend on the number of microfilariae in the blood. The most common side effects are dizziness, nausea, fever, headache, or pain in muscles or joints.

DEC should not be administered to patients who may also have onchocerciasis as DEC can worsen onchocercal eye disease. In patients with loiasis, DEC can cause serious adverse reactions, including encephalopathy and death. The risk and severity of the adverse reactions are related to *Loa loa* microfilarial density.

APPLIED ZOOLOGY AND LAB WORK

The drug ivermectin kills only the microfilariae, but not the adult worm; the adult worm is responsible for the pathology of lymphedema and hydrocele.

Some studies have shown adult worm killing with treatment with doxycycline (200mg/day for 4–6 weeks).

Patients with clinical symptoms

Lymphedema and elephantiasis are not indications for DEC treatment because most people with lymphedema are not actively infected with the filarial parasite.

To prevent the lymphedema from getting worse, patients should ask their physician for a referral to a lymphedema therapist so they can be informed about some basic principles of care such as hygiene, exercise and treatment of wounds.

Patients with hydrocele may have evidence of active infection, but typically do not improve clinically following treatment with DEC. The treatment for hydrocele is surgery.

Prevention and Control

The best way to prevent lymphatic filariasis is to avoid mosquito bites. The mosquitoes that carry the microscopic worms usually bite between the hours of dusk and dawn. If you live in an area with lymphatic filariasis:

- at night
 - sleep in an air-conditioned room or
 - sleep under a mosquito net
- between dusk and dawn
 - wear long sleeves and trousers and
 - Use mosquito repellent on exposed skin.

Another approach to prevention includes giving entire communities medicine that kills the microscopic worms -- and controlling mosquitoes. Annual mass treatment reduces the level of microfilariae in the blood and thus, diminishes transmission of infection. This is the basis of the global campaign to eliminate lymphatic filariasis.

Experts consider that lymphatic filariasis, a neglected tropical disease (NTD), can be eradicated and a global campaign to eliminate lymphatic filariasis as a public health problem is under way. The elimination strategy is based on annual treatment of whole communities with combinations of drugs that kill the microfilariae. As a result of the generous contributions of these drugs by the companies that make them, tens of millions of people are being treated each year. Since these drugs also reduce levels of infection with intestinal worms, benefits of treatment extend beyond lymphatic filariasis. Successful campaigns to eliminate lymphatic filariasis have taken place in China and other countries.

9.12 SCHISTOSOMA

Systematic Position

Phylum- Platyhelminthes

Class- Trematoda

Subclass- Digenea

Order- Strigeidida

Family- Schistosmatidae

Genus- *Schistosoma*

Species- *mansoni*

General characters

- It is a digenetic blood fluke parasitic trematode.
- It is found near the moist places.
- This parasite resides inside the blood vessels of primary host.
- Adult worms reside in pairs.
- Its secondary host is snail.
- Sexes are separate.
- The female lives inside the gynecophoral canal of male.
- Female lay enormous eggs.
- Many larval forms are found in its life cycle like miracidium & cercaria.
- They secrete hepatic enzyme which helps in feeding.

Schistosomiasis, also known as bilharzia, is a disease caused by parasitic worms. Although the worms that cause schistosomiasis are not found in the United States, more than 200 million people are infected worldwide. In terms of impact this disease is second only to malaria as the most devastating parasitic disease. Schistosomiasis is considered one of the Neglected Tropical Diseases (NTDs).

The parasites that cause schistosomiasis live in certain types of freshwater snails. The infectious form of the parasite, known as cercariae, emerges from the snail, hence contaminating water. You can become infected

APPLIED ZOOLOGY AND LAB WORK

when your skin comes in contact with contaminated freshwater. Most human infections are caused by *Schistosoma mansoni*, *S. haematobium*, or *S. japonicum*.

Schistosomiasis occurs in places with poor sanitation. School-age children who live in these areas are often most at risk because they tend to spend time swimming or bathing in water containing infectious cercariae.

If you live in, or travel to, areas where schistosomiasis is found and are exposed to contaminate freshwater, you are at risk.

Areas where human schistosomiasis is found include:

- *Schistosoma mansoni*
 - Distributed throughout Africa: There is risk of infection in freshwater in southern and sub-Saharan Africa—including the great lakes and rivers as well as smaller bodies of water. Transmission also occurs in the Nile River valley in Sudan and Egypt
 - South America: including Brazil, Suriname, Venezuela
 - Caribbean (risk is low): Dominican Republic, Guadeloupe, Martinique, and Saint Lucia.
- *S. haematobium*
 - Distributed throughout Africa: There is risk of infection in freshwater in southern and sub-Saharan Africa—including the great lakes and rivers as well as smaller bodies of water. Transmission also occurs in the Nile River valley in Egypt and the Mahgreb region of North Africa.
 - found in areas of the Middle East
- *S. japonicum*
 - found in Indonesia and parts of China and Southeast Asia
- *S. mekongi*
 - found in Cambodia and Laos
- *S. intercalatum*
 - found in parts of Central and West Africa.

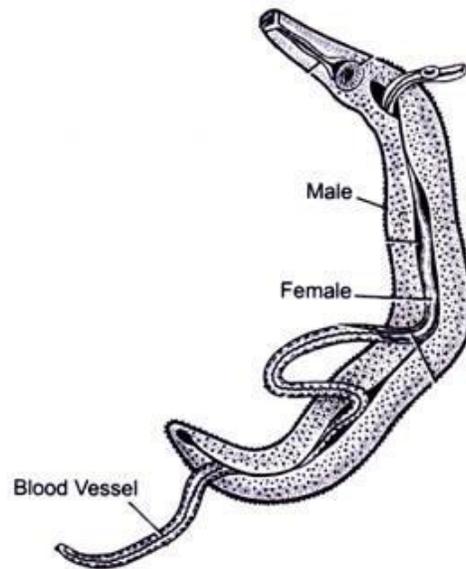

Fig 9.17 *Schistosoma mansoni*

LIFE-CYCLE

Adult worms reside in pairs: the female lying in the gynecophoral canal of the male. After fertilization, eggs are passed into the venules. A larval form – the miracidium - develops within the egg. Its lytic enzymes and the contraction of the venule rupture the wall of the venule liberating the egg into the perivascular tissues of the intestine or urinary bladder. The eggs pass into the lumens and organs and are evacuated in the feces or the urine. On contact with fresh water the miracidia hatch from the eggs and swim about until they find the appropriate intermediate host, snail, which they penetrate. After two generations of sporocyst development and multiplication within the snail, the fork-tailed cercariae emerge. Infection to man takes place during bathing or swimming. The cercariae penetrate the skin and are carried into the systemic circulation and pass through to the portal vessels grow & mature Within the intra hepatic portion of the portal system, the worms feed and grow to maturity.

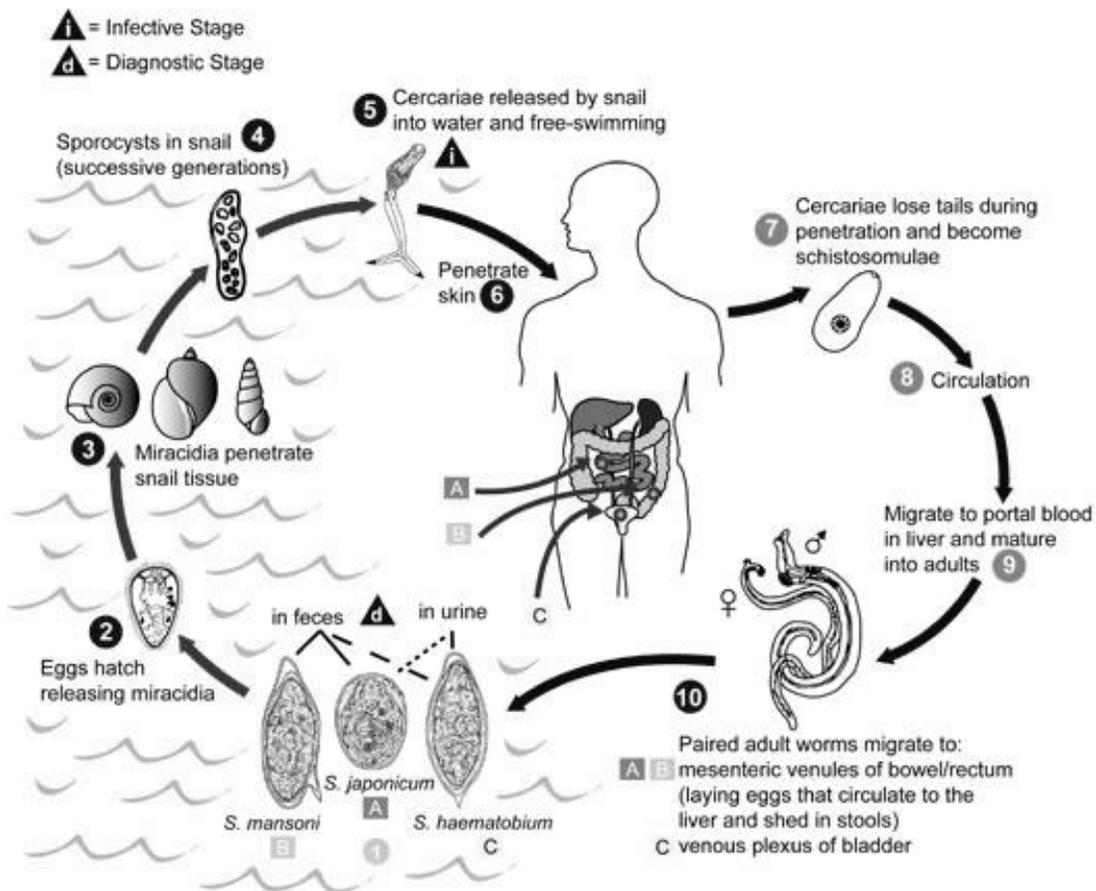

Fig 9.18 Life cycle *Schistosoma mansoni*

Eggs are eliminated with feces or urine. Under optimal conditions the eggs hatch and release miracidia, which swim and penetrate specific snail intermediate hosts. The stages in the snail include 2 generations of sporocysts and the production of cercariae. Upon release from the snail, the infective cercariae swim, penetrate the skin of the human host, and shed their forked tail, becoming schistosomulae. The schistosomulae migrate through several tissues and stages to their residence in the veins. Adult worms in humans reside in the mesenteric venules in various locations, which at times seem to be specific for each species. For instance, *S. japonicum* is more frequently found in the superior mesenteric veins draining the small intestine, and *S. mansoni* occurs more often in the superior mesenteric veins draining the large intestine. However, both species can occupy either location, and they are capable of moving between sites, so it is not possible to state unequivocally that one species only occurs in one location. *S. haematobium* most often occurs in the venous plexus of bladder, but it can also be found in the rectal venules. The females (size 7 to 20 mm; males slightly smaller) deposit eggs in the small venules of the portal and perivesical systems. The eggs are moved progressively toward the lumen of the intestine (*S. mansoni* and *S. japonicum*) and of the bladder and ureters

APPLIED ZOOLOGY AND LAB WORK

(*S. haematobium*), and are eliminated with feces or urine, respectively. Pathology of *S. mansoni* and *S. japonicum* schistosomiasis includes: Katayama fever, hepatic perisinusoidal egg granulomas, Symmers' pipe stem periportal fibrosis, portal hypertension, and occasional embolic egg granulomas in brain or spinal cord. Pathology of *S. haematobium* schistosomiasis includes: hematuria, scarring, calcification, squamous cell carcinoma, and occasional embolic egg granulomas in brain or spinal cord.

Human contact with water is thus necessary for infection by schistosomes. Various animals, such as dogs, cats, rodents, pigs, horses and goats, serve as reservoirs for *S. japonicum*, and dogs for *S. mekongi*.

PATHOGENECITY

Schistosomiasis is caused by digenetic blood trematodes. The three main species infecting humans are *Schistosoma haematobium*, *S. japonicum*, and *S. mansoni*. Two other species, more localized geographically, are *S. mekongi* and *S. intercalatum*. In addition, other species of schistosomes, which parasitize birds and mammals, can cause cercarial dermatitis in humans.

Schistosoma causes schistosomiasis. Patients infected with it suffer from terminal haematuria and painful micturition. There is inflammation of the urinary bladder (cystitis), and enlargement of spleen and liver cercarial dermatitis (swimmers itch) and dysentery (mucus and blood in stool with tenesmus) as well as enlargements of the spleen and liver.

Infection occurs when skin comes in contact with contaminated freshwater in which certain types of snails that carry the parasite are living. Freshwater becomes contaminated by *Schistosoma* eggs when infected people urinate or defecate in the water. The eggs hatch, and if the appropriate species of snails are present in the water, the parasites infect, develop and multiply inside the snails. The parasite leaves the snail and enters the water where it can survive for about 48 hours. *Schistosoma* parasites can penetrate the skin of persons who come in contact with contaminated freshwater, typically when wading, swimming, bathing, or washing. Over several weeks, the parasites migrate through host tissue and develop into adult worms inside the blood vessels of the body. Once mature, the worms mate and females produce eggs. Some of these eggs travel to the bladder or intestine and are passed into the urine or stool.

Symptoms of schistosomiasis are caused not by the worms themselves but by the body's reaction to the eggs. Eggs shed by the adult worms that do not pass out of the body can become lodged in the intestine or bladder, causing inflammation or scarring. Children who are repeatedly infected can develop anemia, malnutrition, and

APPLIED ZOOLOGY AND LAB WORK

learning difficulties. After years of infection, the parasite can also damage the liver, intestine, spleen, lungs, and bladder.

Common Symptoms

Most people have no symptoms when they are first infected. However, within days after becoming infected, they may develop a rash or itchy skin. Within 1-2 months of infection, symptoms may develop including fever, chills, cough, and muscle aches.

Chronic schistosomiasis

Without treatment, schistosomiasis can persist for years. Signs and symptoms of chronic schistosomiasis include: abdominal pain, enlarged liver, blood in the stool or blood in the urine, and problems passing urine. Chronic infection can also lead to increased risk of bladder cancer.

Rarely, eggs are found in the brain or spinal cord and can cause seizures, paralysis, or spinal cord inflammation.

Diagnosis and Treatment

Stool or urine samples can be examined microscopically for parasite eggs (stool for *S. mansoni* or *S. japonicum* eggs and urine for *S. haematobium* eggs). The eggs tend to be passed intermittently and in small amounts and may not be detected, so it may be necessary to perform a blood (serologic) test.

Safe and effective medication is available for treatment of both urinary and intestinal schistosomiasis. Praziquantel, a prescription medication, is taken for 1-2 days to treat infections caused by all *Schistosoma* species.

Prevention and Control

Prevention

No vaccine is available.

The best way to prevent schistosomiasis is to take the following steps if you are visiting or live in an area where schistosomiasis is transmitted:

- Avoid swimming or wading in freshwater when you are in countries in which schistosomiasis occurs. Swimming in the ocean and in chlorinated swimming pools is safe.
- Drink safe water. Although schistosomiasis is not transmitted by swallowing contaminated water, if your mouth or lips come in contact with water containing the parasites, you could become infected. Because

APPLIED ZOOLOGY AND LAB WORK

water coming directly from canals, lakes, rivers, streams, or springs may be contaminated with a variety of infectious organisms, you should either bring your water to a rolling boil for 1 minute or filter water before drinking it. Bring your water to a rolling boil for at least 1 minute will kill any harmful parasites, bacteria, or viruses present. Iodine treatment alone will not guarantee that water is safe and free of all parasites.

- Water used for bathing should be brought to a rolling boil for 1 minute to kill any cercariae, and then cooled before bathing to avoid scalding. Water held in a storage tank for at least 1 - 2 days should be safe for bathing.
- Vigorous towel drying after an accidental, very brief water exposure may help to prevent the *Schistosoma* parasite from penetrating the skin. However, do not rely on vigorous towel drying alone to prevent schistosomiasis.

Those who have had contact with potentially contaminated water overseas should see their health care provider after returning from travel to discuss testing.

Control

In countries where schistosomiasis causes significant disease, control efforts usually focus on:

1. reducing the number of infections in people and/or
2. eliminating the snails that are required to maintain the parasite's life cycle.

For all species that cause schistosomiasis, improved sanitation could reduce or eliminate transmission of this disease. In some areas with lower transmission levels, elimination of schistosomiasis is considered a "winnable battle" by public health officials.

Control measures can include mass drug treatment of entire communities and targeted treatment of school-age children. Some of the problems with control of schistosomiasis include:

1. Chemicals used to eliminate snails in freshwater sources may harm other species of animals in the water and, if treatment is not sustained, the snails may return to those sites afterwards.
2. For certain species of the parasite, such as *S. japonicum*, animals such as cows or water buffalo can also be infected. Runoff from pastures (if the cows are infected) can contaminate freshwater sources.

9.13 SUMMARY

Parasites include one of the most important interactions in the living world which has wide variations in degree & in its impact on the host. A truly successful parasite obtains nutrients & shelter from host. The parasites

APPLIED ZOOLOGY AND LAB WORK

which produce injury to their hosts are pathogens. While parasites are adapted to living in or on their hosts, they can only survive by producing offspring capable of finding new hosts. The key to understanding their dispersal through the world is through knowledge of their life-cycles or modes of transmission.

About two dozen species of parasitic protozoans are found to be getting their nutrition on human -beings, Protozoans which are parasitic on human-beings cause serious disease to man, these are characterized by obligatory nature, host specificity, secretion of toxic substance & having more than one host.

Some common human protozoan parasites are Entamoeba, Trypanosoma, Leishmania, Giardia etc. Entamoeba is a monogenetic parasite of humans causing amoebic dysentery, transmitted through infected food & water. Trypanosoma is a digenetic parasite of human blood causing lymphadenitis; it is transmitted by Tse-tse fly a vector.

Leishmania is the causative agent of kala-azar or visceral leishmaniasis, it is a digenetic parasite spread by vector sand fly. Giardia is a flagellated protozoan causing diarrhoea in human-beings; transmission takes place with contaminated food & water.

Nematodes are generally termed as round worms, they inhabit fresh water, salt water, animal & plant tissues. They are pseudocoelomate, worm like, cylindrical with unsegmented body & unisexual in nature. Ascaris is commonly called as round worm & causes ascariasis which is most common in childrens; it is transmitted through unhygienic food, water & sanitary habits.

Ancylostoma is commonly known as hook worm, it causes ancylostomiasis & infective stage is filarial larva which penetrates the skin of the feet & reaches the lungs.

Enterobius is commonly called as Pin worm & the most common parasite of humans. It causes appendicitis & anal region infections, good sanitary habits help in its prevention. Wuchereria is commonly called as Filaria worm & causes disease filariasis. It is spread by the vector a mosquito (*Culex fatigans*), eradication of its vector is the best prevention of the parasite.

Helminthes are generally leaf like with body covered by cuticle, they have organs of attachment. Schistosoma is commonly known as Blood fluke & found mainly in the blood vessels of human beings. It causes disease schistosomiasis, for completion of its life cycle it needs water & intermediate host snail. It has three larval forms miracidium, cercaria & metacercaria respectively. Metacercaria is the infective stage of the parasite.

9.14 SELF ASSESSMENT QUESTION

Long Answers Type Questions

1. Describe the pathogenesis of Entamoeba?
2. What is the flagellated responsible for causing kala azar?
3. What are the common characteristics of leishmania?
4. With the help of labelled diagram explain the life-cycle of Trypanosoma?
5. Write a detailed note on parasitic adaptations in Ascaris?
6. What disease is caused by Ancylostoma?
7. Describe the life history of *Wucheria bancrofti*?

Short Answer Type Questions

1. Name the primary & intermediate host of Trypanosoma?

Ans: Human being's are the primary host where as Tsetse fly (*Glossina*) is the intermediate host.

2. Name the polymorphic forms of Schistosoma?

Ans: Miracidium & Cercaria larvae.

3. What is the causative organism of Kala-azar?

Ans: *Leishmania donovani* is the causative organism of kala-azar.

4. Name the disease caused by Entamoeba?

Ans: The disease caused by entamoeba is amoebic dysentery or amoebiasis.

5. Maximum number of eggs released by single female Ascaris in a day?

Ans: A single female Ascaris can release upto 2,00,000 eggs in a day.

Fill in the blanks:

1. Giardia is commonly called as.....
2. Schistosoma is..... in nature.
3. Enterobius is.....
4. is commonly used as a worm drug.
5. Zoological name of sand-fly is.....

Multiple Choice Questions

1. Microfilaria is larva of:
 - (a) Tapeworm
 - (b) Pin worm
 - (c) Mud worm
 - (d) Filarial worm

2. Enterobius is generally known as:
 - (a) Pin worm
 - (b) Whip worm
 - (c) Eye worm
 - (d) Gut worm

3. Ascaris is:
 - (a) Host
 - (b) Bisexual
 - (c) Dioecious
 - (d) Digenetic

4. Pre-cystic stage of Entamoeba is called:
 - (a) Magna form
 - (b) Minuta form
 - (c) Feeding form
 - (d) Growing trophozoite

5. Leptomonad form of leishmania is found in:
 - (a) Man
 - (b) Sand fly
 - (c) Tsetse fly

(d) Bed fly

6. Trypanosoma lives inside the human body in

(a) lymph

(b) blood

(c) fluid

(d) none

Answer:

Fill in the blanks:

1. Grand Old Man of the Intestine

2. Sanguivorous

3. Monogenetic

4. Piperazine

5. Phlebotomus

Multiple Choice Questions:

1. d

2. a

3. c

4. b

5. b

6. b

9.15 GLOSSARY

Autoinfection: self infection

Blepharoplast: A small granule-like body, usually appearing in the cytoplasm, from which an axoneme arises. Axonemes may form rod-like structures in the cytoplasm, cilia, or flagella.

Cercaria :The free-swimming larva of a trematode (usually possessing a tail) which escapes from a sporocyst or redia generation within the intermediate, molluscan host and constitutes the transfer stage to the next host

.Chyluria: lymphatic fluid

APPLIED ZOOLOGY AND LAB WORK

Commensal: An association, usually an obligate one, in which an organism lives on or in another, usually larger organism (the host) and derives its nourishment from the host organism without causing damage to the latter

Contamination: The general meaning of this term is clear in that it refers to feces in the context of parasitic disease, however, it should be remembered that a contaminated object is not necessarily infective in as much as the parasite may not be in its infective stage.

Cyst: An organism together with the enveloping membrane or wall secreted by that organism; the stage of a protozoan in which the organism is encased in a "cyst wall "; an encysted organism; a protected or more resistant stage that may be involved in transmission to a new host.

Definitive host: An animal that harbors a parasite where it reaches sexual maturity in or on it.

Digenetic: Three or more generations (literally "two", adult and larval) required for completion of one life cycle (or generation), as in digenetic trematodes. In parasitology, application of this term is virtually limited to those trematodes requiring one or more intermediate hosts

Filariform: (juvenile) A post-feeding-stage, of a nematode characterized by its delicate, elongate structure and its slim, capillary esophagus. Also, the infective stage of hookworm, filarial worms, and some other nematodes.

Gynecophoral canal: This is a canal in the male schistosome where the adult female worm is carried.

Haematuria: Presence of blood in the urine

Hermaphrodite: having both sexes in one

Infective Stage: That stage in the life cycle of a parasite during which it is capable of producing infection

Intermediate host: Hosts normally infected with certain parasites, which are also capable of infecting humans.

Molluscicide: Chemical used to kill snails

Proglottid: a unit of tapeworm body

Trophozoite: The active, vegetative stage of a protozoan.

UNIT 10: COLD WATER AQUACULTURE AND ITS SCOPE IN UTTARAKHAND

10.1 Objectives

10.2 Introduction

10.3 Scope of aquaculture for sustainable livelihood

10.4 Aquaculture of cold water fishes

10.5 Polyculture of carps

10.6 Sewage feed fisheries

10.7 Summary

10.8 Terminal Questions and Answers

10.1 OBJECTIVES

After studying this module, you shall be able to learn and understand :

- Coldwater Fisheries
- Scope of aquaculture for sustainable livelihood in Uttarakhand
- Aquaculture of cold water fishes
- Polyculture of carps
- Sewage feed fisheries

10.2 INTRODUCTION

Fisheries is an economic activity that involves harvesting fish directly from the natural resources (Capture Fisheries) or culture them in confinement (Aquaculture). It may be Traditional/ Small Scale Fisheries for sustenance, or Large-Scale/ Commercial Fisheries for profit. From very ancient time, the fishes are the component of food and also as a great source of commerce and recreation. They also provide us a number of by products which are very useful for humans and their economic value is very high. Due to this, people started Aquaculture to fulfill their food and economic needs. Fish culture is a very ancient industry and nowadays it has become a large industry and is known as Pisciculture

The development of the hilly state of Uttarakhand requires a strong and comprehensive economic base. The economic development of the state can be given a new dimension through proper scientific and commercial use of the available natural resources. The state, is a very rich in terms of water resources. There is immense wealth of water resources which exist in the form of rivers, lakes, reservoirs and ponds. Due to the mountainous landscape and cold climate, the water resources here are cold water as well as pollution-free. The province is also fortunate in terms of biodiversity. Along with the diversity of many organisms and plants, about 100 species of cold water fish are found in the natural water sources here. From fisheries view point, waters of temperatures falling within the tolerance limits of the trouts belonging to the family Salmonidae are termed as cold. Such temperature limits are 0o C to 20o C with an optimum range from 10o – 12oC. In India, lakes and streams located 914 m above mean sea level where the Indian major carps do not live, qualify for coldwaters. The characteristics of coldwater lakes include high oxygen, low carbon

dioxide, inorganic soil, sparse vegetation and food, low fertility and high transparency. The rearing of almost all native and Chinese fishes is prevalent here. Given the breadth of water resources, the diversity of fish species and the importance of fisheries industry at present, cold aquatic fisheries in the State of Uttarakhand. The state's strong fisheries industry is very important for the development of the state, it can make the broad economic base for the development of rural people by giving employment to the rural people and common man. Polyculture or composite fish culture is based on the concept of total utilization of different trophic and spatial niches of a pond which results in maximum fish production. The combination of different fish species gives better utilization of available natural food in a pond. The compatible fish species having different feeding habits are reared so that all the niches of pond ecosystem are properly utilised. In order to obtain high production per ha of water body, fast growing compatible species of fish of different feeding habits, or different weight classes of the same species, are stocked together in the same pond so that all its ecological niches are occupied by the fishes. This system of pond management is called mixed farming or composite fish culture or polyculture.

The farmers observed that there were differences in the feeding habits and different preferences for natural food organisms. This led to the thought of adjusting the stocking densities according to the occurrence of natural food and the niche occupied by each species in the ponds. Thus, it could be beneficial in traditional production systems by culturing appropriate species combinations. Such a practice could effectively lead to the utilisation of a much larger quantity of food resources and developing a symbiotic relationship between the cultured species in the system. This would lead to higher production at a lower cost and the farm environment can be maintained at required levels.

Sewage is universally considered as a valuable organic fertilizer as it contains abundant quantities of nutrient elements. In general way, the term sewage is used for a combined liquid waste discharged from all domestic, municipal and industrial sources within a given area. Sewage fed fisheries is a new idea for India. Fish culture in sewage system involves little investment with high yield. A sewage itself provides fertilizers and supplemented food to pond. This reduces the cost of culture and at the same time the growth rate of fish in such ponds is also faster. In India the practice of sewage fed fisheries is not very popular.

10.3 SCOPE OF AQUACULTURE FOR SUSTAINABLE LIVELIHOOD

In terms of the scenario of economy of India, fisheries plays an important role by providing food security, generating big employments and also small livelihoods, and earning foreign exchange for the country.

Uttarakhand, one of the Hilly states of India has enormous freshwater fisheries resources that comprised of 2,700 km of rivers, 24,200 hectares of reservoirs, 297 hectares of lakes and about 2000 hectares of ponds. The state comprises two major regions namely Kumaon and Garhwal and both the regions are blessed with an abundance of aquatic resources. Since, water temperature in the hills falls below 20°C, the exotic carps (common, grass and silver carps), mahseers and other such coldwater fishes that can grow and survive at lesser temperature are more suitable for use in hill aquaculture. Among all the cultured species; Silver carp, Grass carp and Common carp are reported to perform better in composite culture system in the mid altitude conditions. Common carp plays an important role in augmenting fish production especially in the hill states of the region. Since the size of fish ponds in the hill areas are small and principally rain fed and seasonal, the small-scale integrated aquaculture utilizing available on-farm resources has great potential.

Food and nutritional security are global challenges. It is more of a problem in the hilly region; there are both challenges and opportunities in hill fisheries and aquaculture. Mountain states are the major hilly regions, which have a huge scope for coldwater fisheries and aquaculture. Fish is a healthy food and is a rich source of all nutrients (except carbohydrates) and in combination with rice/wheat (carbohydrate rich) make a complete diet. Most of the coldwater fishes are quiet nutritious with high proteins (16-18%) and are moderately rich in oils (*Labeo dyocheilus* 5.7%, *Tor putitora*, 4.3%) and the polyunsaturated fatty acids (PUFAs), EPA in *Schizothorax richardsonii* and DHA in *T. putitora*. The PUFA content of some of the coldwater fishes are comparable or close to the marine fishes. Some coldwater fishes are very rich in essential amino acids arginine (*T. putitora*) and tyrosine (*T. putitora*). Similarly, some of them are rich in micronutrients calcium (*N. hexagonolepis*), iron (*N. hexagonolepis*) and zinc (*Cyprinus carpio*). If the coldwater fisheries and aquaculture production reach its potential, it

APPLIED ZOOLOGY AND LAB WORK

could not only provide nutritional security to the hilly region but would ensure livelihood security also, owing to their nutritional richness. Thus, the coldwater fisheries and aquaculture sector needs special focus for increasing farmer's income as well as providing nutritional and livelihood security to the hill people. Understanding it, the aquatic resources in hills are quite valuable for the development of fishery both for food, sport, recreation and employment but scientific management of these resources is necessary to achieve the objectives. In order to manage these ecosystems, it is necessary to take up appropriate strategic plans and action so that hill aquatic resources and aquaculture activities may contribute to fishery and aquaculture substantially in remote hilly regions on a sustainable basis.

There is a vast scope and potential in improving fish production in hills by bringing natural Himalayan lakes located at different altitudes, under scientific management for fishery enhancement. This would actually reduce the gap between actual fish yield and production potentials. Through application of modern techniques, significant scope exists for promoting trout farming, which in long run, will have both domestic and export demand. There is also a great potential for sport fishery development and ecotourism in hill regions. Use of modern techniques such as molecular and biotechnological intervention, selective breeding programme for improvement of strains both of exotic and indigenous species, coldwater fish health management for the containment of diseases have now become imperative. Ornamental fish culture for small scale enterprises in the hills can provide an alternative source of employment.

10.4 AQUACULTURE OF COLD WATER FISHES

India has significant coldwater fishery resources in terms of gene pool, and some of them being suitable for food, sport and ornamental purpose. The Coldwater natural resources includes around 8243 km long streams and rivers, 20500 ha natural lakes, 50000 ha of reservoirs both natural and manmade and 2500 ha brackish water lakes at high altitude. Coldwater fishes occupy an important place amongst the freshwater fishes of India. The coldwater fisheries deal with fisheries activity in water where temperature of water ranges from 5 to 20 degrees centigrade. The gills of cold water fish are greatly reduced and the gill opening are smaller in size for adaptation to cold temperatures. Important coldwater fishes of India are Mahseers such as *Tor putitora*, *T. tor*, *T. khudree*, *T. mosal*, Snow Trout such as *Schizothorax richardsonii* and *Schizothoraichthys socinus*, Mountain Trout such as *Barilius vagra*, *B. bendelisis*, other fish

APPLIED ZOOLOGY AND LAB WORK

such as *Glyptothorax sp.*, *Garra sp.*, etc. **Exotic trouts:** *Onchorhynchus mykiss*, *Salmo trutta fario*. **Exotic carps:** *Cyprinus carpio var. specularis* *C. carpio var. communis* *C. Carpio Var. nudus* *Ctenopharyngodon Idella*, *Hyphthalmichthys molitrix*, *Carrasius carrasius*. **Minor carps:** *Labeo dyocheilus*, *Labeo dero*, *Chagunius chagunio*, *Crossocheilus latius latius* *Garagotyla*, *G. hughi*, **Barils/Minnows/Catfishes/ Loaches:** *Barilius bendelisis* *B. bakeri* *B. vagra* *B. barila* *Raimas bola* *Danio divario* *Botiabirdi* *Glyptothorax pectinopterus* *G. conirostre conirostre*. The state Uttarakhand is blessed with plenty of natural beauty, including ice covered Himalayan Peaks and centre of beauty is many freshwater streams and snow fed rivers all along the landscape. The head water of the holy river Ganges such as Alaknada and Bhagirathi rivers take origin from Garwal Himalaya and the other major tributaries like Ramganga and Kali river drain along the Kumayan region of Uttarakhand region. The important game fishes reported from this regions are: golden mahseer (*Tor putitora*), silver mahseer (*Tor tor*), goonch (*Bagarius bagarius*), Mully (*Wallago attu*), murrels (*Channa spp.*) and snow trout (*Schizothorax spp.*).

Species of Cold Water Fisheries:

(1) Mahaseer:

There are 4 species of mahaseer. It has a big head hence it is known as Mahaseer. Two of them are edible fishes and are of commercial use, they are *Tor putitora* and *Tor tor*.

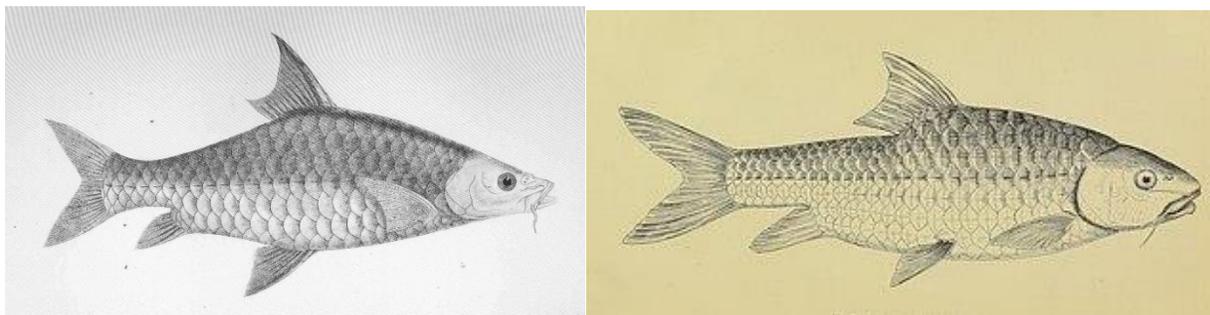

Fig 10.1 :(a) *Tor tor* (b) *Tor putitora*

(2) Snow Trout:

Two genera are present; *Schizothorax Spp.* and *Schizothoraichthys* are endemic to Kashmir and Ladakh while *Schizothoraxprograstus* occurs in Eastern Himalayas up to certain stretch. *Schizothoraxrichardsonii* is distributed almost all along the Himalayas.

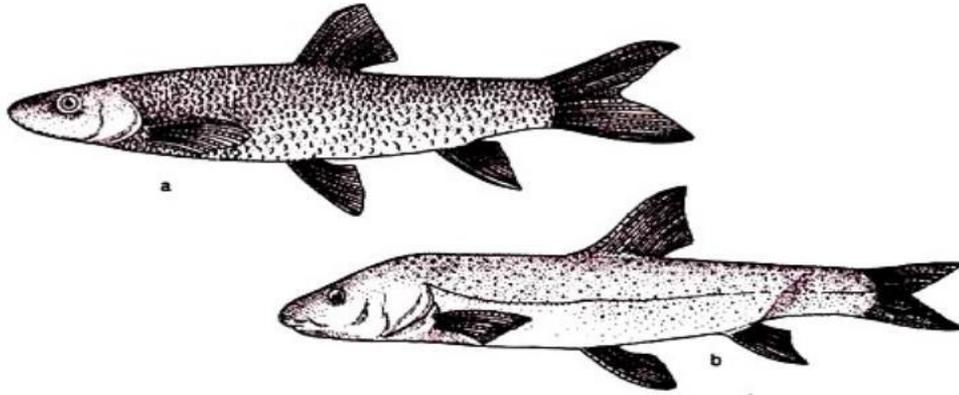

Fig: 10.2 (a)*Schizothorax Spp.*(b)*Schizothoraichthysesocinus*

(3) **Barilius:** *Barilius vagra*, *B. bendelisis* and, *B. bola* fishes are also called as Mountain trouts .

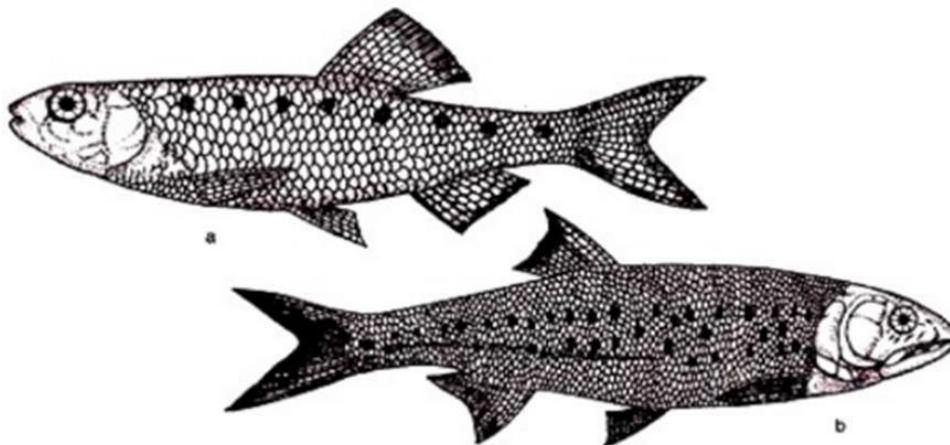

Fig 10.3: (a)*Barilius bendelisis*

(b)*Bariluis bola*

APPLIED ZOOLOGY AND LAB WORK

(4) **Labeo**: The fishes which are present in mountain rivers are minor carp and have no significance as commercial fisheries. The fishes are *L. dero*, *L. dyocheilus* and *Crossocheilus latius*.

(5) **Garra**: There are two species found in lakes of the Himalayas as they are not edible fishes but are relished as food of fishes. They are *Garra lamta* and *Garra gotyla*.

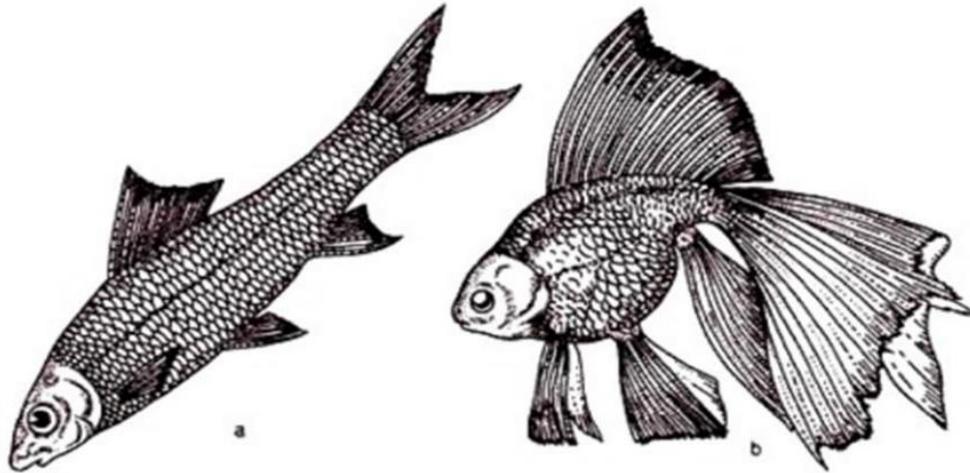

Fig 10.4: (a) *Labeo dero* (b) *Carassius auratus*

Exotic Fishes:

1. Trouts: The few trouts are now acclimatized in the streams, lakes and reservoirs in Indian waters. These are brown trout *Salmo trutta fabrio*, *Salmo eredi*, *Salmo gairdineri* and *Oncorhynchus mykiss* (rainbow trout), *Oncorhynchus nasutus*

2. Cyprinus Carpio: The culture is being successfully done by induced breeding methods.

Flow through Hatchery:

This is a device for rearing fish seed up to the fry stage. It has been designed and fabricated by **National Research Centre on Coldwater Fisheries** at Bhimtal in Kumaun hills. It has the capacity of incubating 0.225 million eggs. The capacity of flow through hatchery further increased with installation of more troughs/ trays and nursery facilities with substantial increase in the quantity of water through overhead tanks. This method gives 30% more survival rate from traditional pattern.

10.5 POLY CULTURE OF CARPS

When different species of fast growing compatible fishes, occupying different ecological niches of a pond or any water body, are cultured together, they most efficiently utilise all the food sources available in the pond for fish production without harming each other.

Objectives of Polyculture:

- (1) To obtain maximum yield or fish production.
- (2) To utilise all the available niches.
- (3) The fishes cultured should not cause any ecological disbalance.
- (4) The fish species cultured should not have any serious competition between them but each species may have a beneficial influence on growth and production of the other. For example, grass carp by consuming aquatic vegetation, converts plant tissue into fish flesh but its excreta fertilises the pond which benefits all other species.
- (5) Some species of fishes are cultured which have specific roles to play in maintaining water quality in ponds by feeding on wastes accumulated in it. For example common carp and mrigal consume the faeces of grass carp and silver carp, which contain large amounts of undigested plant matter.
- (6) Recent combination of fish species cultured are based on one or two species as the main ones and the others as subsidiary compatible species which would be utilising those parts of the food resources that would have been wasted.

Fish used in polyculture

Polyculture method traditionally combines the Indian major carps rohu (*Labeo rohita*); catla (*Catlacatla*); and mrigal (*Cirrhinus cirrhosus*). The research modified the fish composition to include the small carps mola (*Amblypharingodon mola*) and punti (*Puntius sophore*) and the replacement of the bottom feeder mrigal by common carp (*Cyprinus carpio*). Chinese silver carp (*Hypophthalmichthys molitrix*), an inexpensive species that farmer families can afford to eat instead of selling, is currently being tested. Combinations of three Chinese carps (bighead, silver and grass carp) and the common carp are most common in Polyculture. Other species may also be used. While fish may be grouped into broad categories based on their feeding habits, some overlap does occur. In our state Polyculture systems has tremendous potential and our endemic

Schizothoracid species can be utilized effectively in composite fish culture .

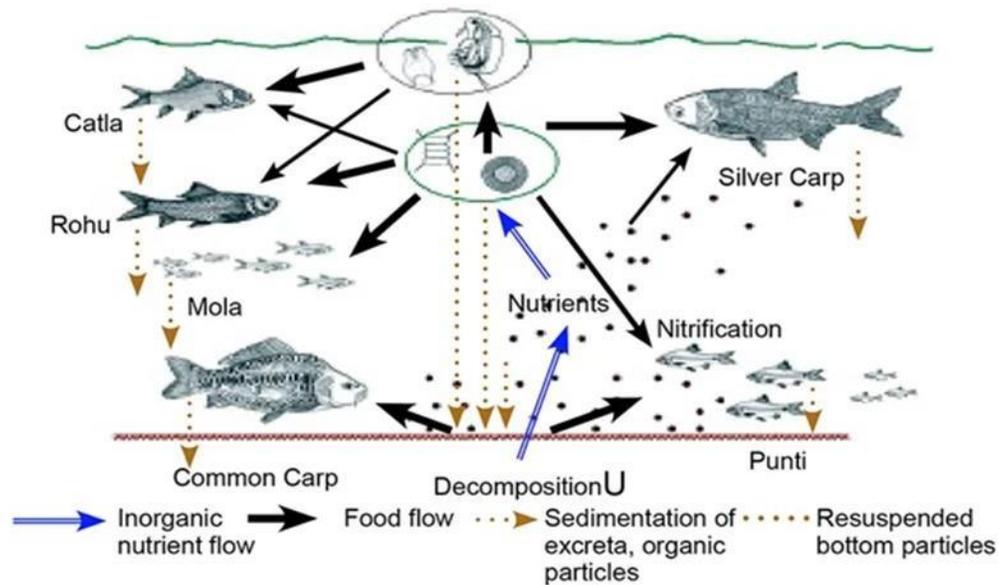

Fig. 10.5. Polyculture of carps

Polyculture is an effective way to maximize benefit from available natural food in a pond. Polyculture or mixed fish farming or composite fish culture is the culture of fast growing compatible species of fishes of different feeding habits (or different weight classes of the same species) in the same pond so as to utilise the various available ecological niches in order to obtain high production per hectare of water body.

A pond according to its depth can be divided into three distinct zones: upper surface zone, middle column zone and bottom zone. A particular species exploits food of a particular zone. For example *Catla* is a surface feeder, *Labeo rohita* a column feeder and *Cirrhinus mrigala* is a bottom feeder.

In case of single species or monospecies or monoculture only one zone will be utilised or exploited while the other zones would remain unutilised. As a result the entire ecological area would not be exploited and the yield or fish production would be less.

(A) Renovation of the Pond:

Generally due to rain and flood the edges or dykes of the ponds may get damaged and a lot of silt or mud may accumulate at the pond bottom, thereby decreasing the depth of water. In such cases

APPLIED ZOOLOGY AND LAB WORK

the entire water of the pond is to be removed through the help of a pump. The pond bottom should be allowed to dry. The humus at the pond bottom should be removed through the help of manual labours. The dykes has to be repaired and plants to be planted on it so that its roots would prevent soil erosion. The pond is then filled with water.

(B) Clearance of Weeds:

One of the crucial problems encountered by Indian pisciculturists is the excessive growth of aquatic vegetation in water bodies and its control.

1. Manual and Mechanical Control:

If the weed infestation is scanty, then it can be easily removed manually with the help of a long bamboo. The entire weeds are swept with the bamboo to a side and then removed manually with the hand. As the weeds grow again, it is difficult to eradicate them completely. In case of denser infestation the weeds can be removed with the help of weed cutter.

2. Chemical Control:

In case of dense weed infestation suitable weedicides may be used. A large variety of chemical herbicides are used as weedicides.

3. Biological Control:

Weeds in a water body can be controlled by means of selected varieties of herbivorous fishes. The important herbivorous fishes used are: grass carp (*Ctenopharyngodonidella*), tawes (*Puntius javanicus*); common carp (*Cyprinus carpio*); *Tilapia mosambica* and gourami (*Osphronemus goramy*).

(C) Eradication of Weed and Predatory Fishes:

It is not desirable to have weed and predatory fishes in the cultural impoundment. Weed fishes by consuming the nutrients from water competes for food, space and oxygen with the fingerlings of culturable carps

The predatory fishes, on the other hand, directly prey on the culturable carp spawn, fingerlings and young fishes. One way of eradicating these unwanted fishes is by dewatering and drying the pond. However, where dewatering is not possible then these fishes have to be killed by the application of fish poison, generally of plant origin. The most widely used fish poison of plant origin is mohua oil cake. The application of *Brassica latifolia* (mohua oil cake) is of much significance in fish ponds because of its role as piscicide in the initial phase of treatment and as manure in later phase after its loss of toxicity.

(D) Addition of Lime:

The first step in fertilisation is the application of lime. The common form used is limestone.

Liming is essential for successful pond manuring. .

(E) Addition of Fertilisers:

(a) Inorganic Fertilisers:

The major fertilising elements are nitrogen, phosphorous, potassium and calcium.

(b) Organic Fertilisers:

Organic fertilisers are either of plant or animal origin. It contains almost all the nutrient elements required in the metabolic cycle. The nutrients locked in them are either made available directly or after decomposition and transformation by the microbes.

Organic Manures

The manures falling under this category are:

- Liquid Manure from Stable and Byres has been found to impart fertility for good fish yield.
- Through the use of dried blood and guano an increase in fish yield has also been reported
- **Oil Cakes:** Oil cakes such as mustard oil cake, mohua oil cake, cotton seed meal, soybean meal, etc. have been used for manuring fish ponds. Mustard oil cake is used either singly or in combination with cowdung.
- **Green Manuring:** Green manuring is used to fertilise fish ponds. In this method green plant tissues are decomposed and turned into soil. This is done by sowing a nitrogenous or other crop on dry pond bottom at the time of pond preparation or by dumping it in a heap at one end of the pond.
- **Compost:** Another good organic manure is compost. It is formed by dumping organic wastes, vegetable debris, cut grass, cow dung, aquatic weeds, etc. into a large pit and then the pit is covered with soil. The aerobic bacteria in the presence of nitrogen convert the above mentioned wastes into humus.

Organic manures with carbohydrates and nitrogenous matter:

(i) Farm Yard Manure

(ii) Poultry Manure

2. Stocking Management

In aquaculture practices only the common carp is cultured in monoculture system. While in poly-

APPLIED ZOOLOGY AND LAB WORK

culture system either the Indian major carps or in combination with the exotic carps are cultured in various combinations. However, prior to the introduction of fry or fingerlings the cultured water has to be tested whether it is suitable for culture or not.

For rearing of carp the main or basic objective is the production of an optimum quantity of the desired size of fish, at minimum cost. There are two systems of stocking that the fish farmers generally adopt:

(i) Multi-Size Stocking:

This involves stocking, in the same pond different sizes (fry, fingerlings and young adults) of fishes in order to utilise the food resources more efficiently. In this system additional stocking of fishes and periodic harvesting of marketable fishes are undertaken.

(ii) Multi-Stage Stocking:

In this system fishes are stocked in progressively larger ponds (nursery, rearing and stocking) as they grow in size. Here, the stocking rates are reduced and harvesting of marketable fishes are done after a period of approximately one year culture.

(B) Species Combination:

Three broad combinations are practised in India, i.e.

- (1) Culture of Indian major carps alone,
- (2) Culture of exotic carps alone and
- (3) Culture of Indian and exotic carps together.

In cases where silver carp is cultured along with catla, the silver carps introduced should be smaller in size and lesser in number.

As silver carp feeds on phyto- plankton, the density of phytoplankton would fall if silver carp is introduced in large numbers. This would hamper the quantity of zooplankton and ultimately the growth rate of catla, that feeds predominantly on zooplankton.

Besides the above, a number of other species are also stocked in polyculture system. The more common ones being tilapia (*Tilapia mosambica*), gouramy (*Osphronemus goramy*), grey mullet (*Mugil parsia*), tawes (*Puntius javanicus*) and a small number of carp hybrids (calbasu male x catla female).

Sometimes a carnivore, chital (*Notopterus chitala*), is added to control weed-fishes. However, this

carnivore should be smaller in size (2 inches to 3 inches) so that they do not prey on carp fingerlings.

Although polyculture envisages compatible combinations of species or age groups that do not compete in feeding habits, but there is often considerable overlap of the feeding habits and preferred food items. When several species are added in ponds, the concept of exclusive ecological niches and special separation are not always applied.

Recent combinations are generally based on one or two species as the main ones (depending upon the market demand) and the others as subsidiary compatible species that will utilise the unutilised food resources or would help in reducing the deterioration of water quality by feeding on the wastes.

(C) Stocking Density and Ratio:

Several stocking rates in different combinations is practised in different areas depending upon the market demand and the size to which it is grown. Under normal management, a stocking rate per ha of 5000-6000 fingerlings of 2.5-5 cm length is grown to a size of 600-1000 g or more in one year or less. A lower stocking density 4000-5000 is recommended if the fishes are to be grown to marketable size in a short time.

Different species of fishes are stocked in varying ratios. The commonly stocked ratio of catla, rohu and mrigal in the ponds of Bengal are 3: 3: 4 (Alikunhi, 1957). Recently, the most commonly stocking ratio is catla 30 per cent, rohu 60 per cent, and mrigal 10 per cent.

3. Post-Stocking Management:

Culture of carps in pond is mainly based on fertilisation and supplementary feeding.

A. Pond Fertilisation:

Fertilisation with inorganic and organic manure helps to meet the requirement of carbon, nitrogen, phosphorous and other nutrients. It is a known fact that manure increases plankton and chironomid production in fish ponds, probably due to high production of bacteria and protozoa developing on the organic matter of the manure. Detritus or the decomposing organic matter has a high protein content.

The stocking density and the environmental conditions of the pond determine the rate of application of fertilisers. Moreover, the dosage and mode of application is also important, whether the entire quantity has to be applied in one lot or sporadically. Too much of nutrients, resulting from manuring may lead to the development of algal bloom, particularly under Indian

APPLIED ZOOLOGY AND LAB WORK

conditions. It may cause clogging of the gills and also depletion of the oxygen concentration in the ponds. Manuring, thus, should not be done during persistent cloudy weather or when algal bloom appears.

(i) Application of Organic Manure:

Raw cow dung is generally used as an organic manure. Under most situations a dose of 100-120 kg (dry matter) per day can be safely used under most situations. Generally in India, the application of organic manure is 10,000- 20,000 kg (wet weight/ha/year).

(ii) Application of Inorganic Manure:

Using chemical fertilisers is advantageous. In intensive culture, where fishes are stocked in higher densities, fertilisation at a dose of 60 kg/ha of single superphosphate and 60 kg/ha ammonium sulphate, every two weeks is considered to be beneficial. In polyculture carp ponds where supplementary feeding is adopted, nitrogen, phosphorous and potassium fertilisers are applied at a ratio of 18: 8:4 at the rate of 500 kg/ ha/year.

(iii) Liming:

Liming should be done monthly, 1 -2 days after the application of organic manure

B. Supplementary Feed:

The spawns after being stocked, start feeding voraciously on zooplankton. Within 2-3 days of stocking, the natural food available in the pond gets depleted. At this time artificial feed along with natural food enhances the growth and survival of spawns. For Indian carps the commonly given feed are rice/ wheat bran and oil cakes of ground-nut, coconut, mustard, etc.

D. Control of Diseases:

Prophylactic treatments with dip or bath in 0.38% potassium permanganate are given to fishes as a precautionary measure. Therapeutic treatments are given to cure parasitic infections and bacterial diseases.

E. Final Netting for Harvesting and Marketing:

Polyculture is generally practised for a period of 10 to 12 months, after which the entire stock is harvested in case of multi-stage stocking. Some farms have marketing ponds where the live fishes are temporarily kept till they are marketed. After harvesting, the catches are sorted out species-wise and size-wise before marketing.

10.6 SEWAGE FEED FISHERIES

Sewage is defined as a cloudy fluid arising out of domestic, municipal and industrial waste, containing mineral and organic matter in solution or having particles of solid matter floating, in suspension, or in colloidal and pseudo-colloidal form in a dispersed state. Sludge differs from sewage in that it is the solid portion of waste and does not include fecal matter urine.

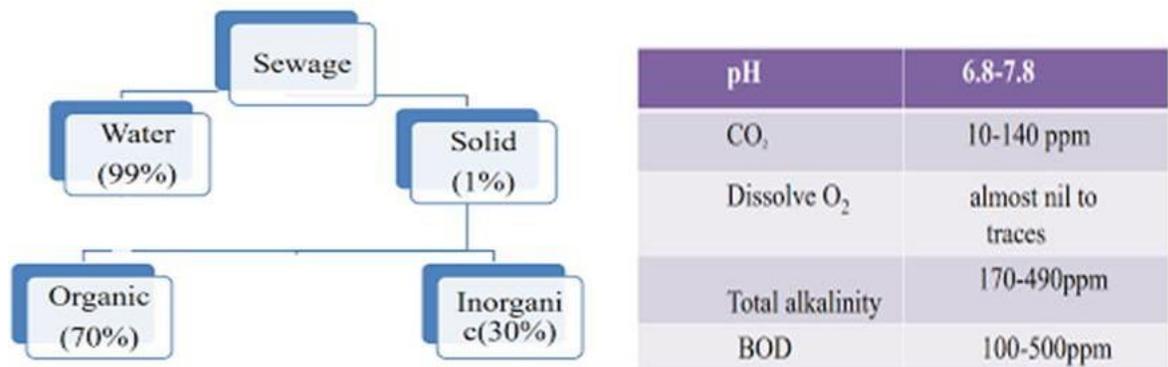

Fig10.6 Physicochemical characteristics of Sewage

Domestic sewage has been reported to contain about 250 – 400 ppm of organic carbon and 80 – 120 ppm of total nitrogen. Thus giving the C:N ratio of around 3:1. Industrial sewage may contain more organic carbon and hence may have a higher C: N ratio. Nitrogen in sewage is present partly as organically bound element and partly as ammonical nitrogen. The fish farmer of Kolkata developed a unique technique of utilization of domestic sewage for fish culture long back in 1930s. The early inspiration of utilizing the sewage for fish culture emerged from the waste. Stabilization pond used as water source of vegetable fields. This technique is considered to be the largest operational system in the world to convert the waste in consumable product. The growing fish demand of the metro city Kolkata is widely met by this technique. Present Status of Sewage Fed Fish Culture . In the course of time the area under sewage-fed fish culture reached up to 12,000 ha. But recently due to rapid and indiscriminate urbanization it

has come down to 4,000 ha. Resulting in crisis of livelihood of rural people. There are appeals to Government to declare the existing sewage-fed aquaculture area as sanctuaries.

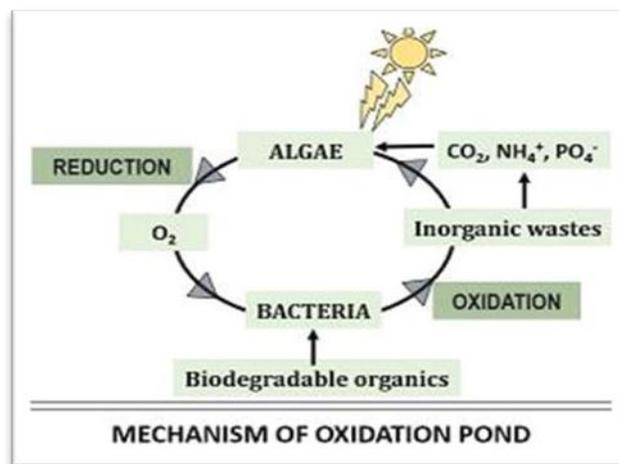

Treatments of Sewage

1. Primary treatment This is mostly the physical removal of solids by mechanical means. The solid material is removed by screening (for larger coarse particles), skimming (for floating solids) and sedimentation (for suspended particles whose density is greater than that of liquid) techniques.

2. Secondary treatment Soluble organic and inorganic matter, namely the carbohydrates, proteins, fats, hydrocarbons and other nitrogenous materials which are degraded mostly biologically, using microorganisms into the smaller constituents i.e. CO₂ , H₂O, NO₃ , NO₂ , SO₄ , PO₄ etc. which can be easily disposed. Some times chemical and physical removals of substances are combined with this to increase the effectiveness. There are three basic methods for secondary treatments: – Activated sludge (flocculation) – Biological filtration – Waste stabilization

3. Tertiary treatment This is biological and chemical removal of soluble products of partial or complete oxidation. For example, removal of NO₃ , NO₂ , SO₄ , PO₄ etc. Physical or chemical removal of refractory organic or other substances which may be unpleasant and even toxic. Chemical treatment comprises of : (a) Coagulation or chemical precipitation (e.g. by alum), (b) Deodorization (by Cl₂ , FeCl₃), (c) Disinfections or sterilization (by Cl₂ , CuSO₄ , liming etc.).

4. Oxidation Pond : Organic matter contained in the waste is stabilized and converted in the pond into more stable matter which find their way into effluents. A conventional oxidation pond contain the algal

APPLIED ZOOLOGY AND LAB WORK

bacterial culture, which oxidizes the organic matter into CO_2 , H_2O , H_2S , NH_3 , and other decomposition products that are used as nutrients like nitrite, phosphate

Filtration There are two types of filtration process, viz., mechanical filtration and biological filtration such as trickling filter which uses filter medium grains covered with biofilm.

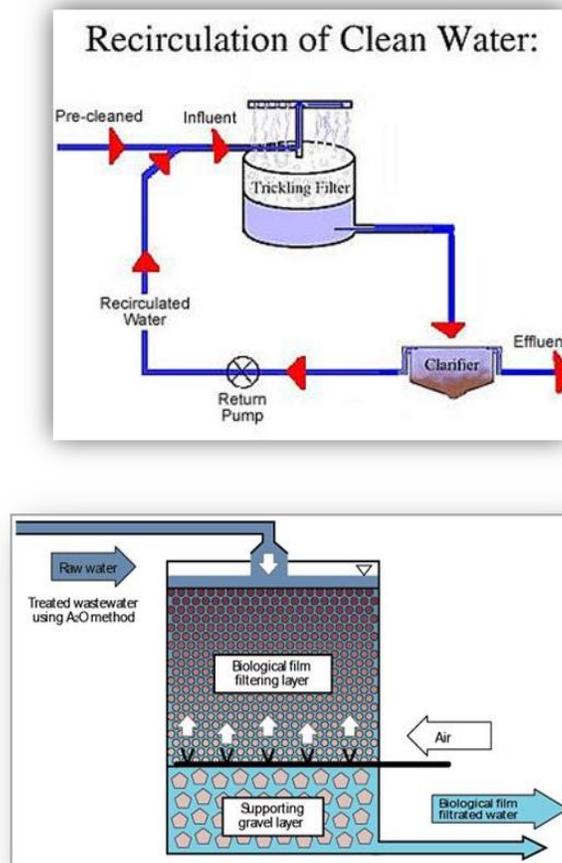

Fig: 10.7 Filtration

The process generally adopted for the use of sewage treatment before release in fish ponds

- Sedimentation
- Dilution
- Storage

APPLIED ZOOLOGY AND LAB WORK

The process generally adopted for the use of sewage treatment before release in fish ponds Sedimentation Dilution Storage Technologies adopted by farmers. The sewage fed ponds are locally known as BHERIES. These are the ponds of different sizes, which can be as big as 40 ha. The ponds are shallow with a depth ranging from 0.5 to 1.5 m. Generally the culture practice includes five phases:

Pond Preparation

1. Sewage fed ponds are pumped out to dry
2. Drying of pond during winter months
3. Bamboo sluice & dikes are repaired

Primary Fertilization

After pond preparation, sewage is passed in to the pond from the feeder canal through bamboo sluice. It is left to stabilize for 15 – 20 days. The self-purification of sewage takes place in presence of atmospheric oxygen and sunlight. When the water turns green due to photosynthetic activity, the pond is considered ready for stocking. Allow sewage flow in pond through open channel

Fig: 10.7 Sewage flow in pond through open channel

Fish Stocking

All the species of Indian major carps e.g. *Labeo rohita* (Rohu), *Catlacatla*, *Cirrhinus mrigala* (Mrigal) and Exotic carps e.g. *Hypophthalmichthys molitrix* (Silver carp), *Ctenopharyngodon Idella* (Grass carp), *Cyprinus carpio* (Common carps) are preferred to be stocked but the

APPLIED ZOOLOGY AND LAB WORK

percentage of Mrigal is kept greater and that of exotic carps is lesser. The popularity of *Talapia* and fresh water prawn, *Macrobrachium rosenbergii* is increasing these days. *Pangasiushypophthalmus* is also stocked by some farmers to get rid of mollusks. As the sewage contains high content of nutrient, the farmers keep very high stocking density, i.e. 40,000 to 50,000 fingerlings/ha.

Secondary Fertilization

After stocking, sewage is taken in ponds throughout the culture period at regular intervals @ 1–10% of the total water volume of the pond. In bigger ponds, water level is maintained by continuous inflow and out flow. The requirement of sewage is determined by observing the water colour, transparency, temperature and depth.

Feeding of stocked fishes

Due to high contents of nutrients in sewage, the cultured fishes don't require at all any supplementary feeding. However, occasionally, especially in rainy season when the potential sewage is lacking, they are fed with supplementary feed.

Health care of fishes

The fishes are most vulnerable to bacterial diseases, but surprisingly the occurrence of bacterial or any other disease is not common in sewage-fed fish farms. Even when EUS was prevailing in past years in other areas, the sewage-fed ponds were uninfected. However, parasitic infections by *Lernea* (Anchor worm) and *Argulus* (Fish lice) are common but they are not given any proper treatment. There is a need to develop a technique to keep these problems aloof.

Harvesting

The BHERI farmers have evolved rotational cropping system to maintain the supply to the market. Fishes are stocked and harvested throughout the culture period leading to periodical stocking and regular harvesting. After completion of one phase, fishes are restocked @ 1 Kg fingerlings per 5 kg harvested fish. Another harvest phase starts after 15 days of restocking. Generally, drag nets are used for harvesting by encircling technique. Some fishes like *Tilapia* and Common carp require hand picking technique for their harvesting. Specialized fishermen are employed in fishing. 7.5 cm long fingerlings of rohu, catla and mrigal stocked in the ratio 1: 1:1 @ 550 kg/ha gave an annual fish production of c. 3,237 kg/ha. The results of further experiments

on the ratio of stocking and the yield/ha of water area. Best results were obtained when the ratio of stocking of rohu, catla and mrigal was 1:2:1. For fish culture sewage water of stabilizing tank as well as the water after dilution can be utilized. Air breathing fishes are more suitable to be cultured in sewage treatment ponds as they can survive in water with lesser dissolved oxygen content. The fish like *Clarias batrachus*, *Heteropneustes fossilis*, *Channa spp.*, *Tilapia mossambicus* and *Ctenopharyngodonidella* (grass carp) are the species of choice to be considered for culture in sewage treated ponds.

10.7 SUMMARY

Cold water Fisheries occupy an very important place amongst the freshwater fisheries of India. The cold water fisheries deals with fisheries activity in water where temperature of water resource ranges from 5 to 25 degrees centigrade. The temperature of water under cold water fisheries should not be more than 25°C even in summer season.

Such conditions occur in Himalayan and peninsular regions of India . There are 16 big and small rivers in Himalayan and peninsular regions having an area of. Government of India established National Research Centre on Cold Water Fisheries in Uttarakhand at Bhimtal. It has played a significant role in the aquaculture improvement and conservation of indigenous as well as in the successful survival of exotic species of fishes in this region. The survival at high altitude depend upon several factors resulting in different adaptations in fishes. The torrential streams of water in mountain region is rich in oxygen and low in carbon di-oxide quantity, the parameters of which are very important for the growth of fishes.

In the cold-climate State of Uttarakhand, the general public needs a protein-rich digestible, easy-to-eat food. Fish can provide good nutrition. Cold aquatic fish species like Mahashir and Trout have always been the choice of hunting lovers. By organizing the fishing areas in the beautiful places of Uttarakhand and more, tourism of the state can be made attractive and economically beneficial.

Fish as a source of Protein will provide abundant nutrition as well as become an assured synonym for future food security. In addition to animal protein, fish contain unique long-chain poly-unsaturated fatty acids (LC-PUFAs) and highly bioavailable essential micronutrients—

APPLIED ZOOLOGY AND LAB WORK

vitamins D and B, minerals (calcium, phosphorus, iodine, zinc, iron, and selenium). These compounds, often not readily available elsewhere in diets, have beneficial effects for adult health and child cognitive development (HLPE, 2014). So, fisheries can effectively play a role in economic development, food provision, and ultimately poverty alleviation and reducing malnutrition. This requires the implementation of a comprehensive project with a scientific and professional basis. The species being more tasty and nutritious sells at higher prices in the market and at the same time has good demand in the international market. The export of these fish is likely to generate good foreign exchange in the State.

The possibilities of increasing fish production per unit area, through polyculture, is considerable, when compared with monoculture system of fish. Polyculture is the practice of culturing more than one species of aquatic organism in the same pond. The motivating principle is that fish production in ponds may be maximized by raising a combination of species having different food habits. Different species combination in polyculture system effectively contribute also to improve the pond environment. Algal blooming is common in most tropical manure fed ponds. By stocking phytoplanktophagus Silver carp in appropriate density certain algal blooming can be controlled. Grass carp on the other hand keeps the macrophyte abundance under control due to its macrovegetation feeding habit and it adds increased amount of partially digested excreta which becomes the feed for the bottom dweller coprofagous common carp. The bottom dwelling mrigal, common/mirror carp help re-suspension of bottom nutrients to water while stirring the bottom mud in search of food. Such an exercise of bottom dwellers also aerates the bottom sediment. All these facts suggest that polyculture is the most suitable proposition for fish culture in undrainable tropical ponds.

With the purpose of getting maximum production of fishes from a water body (lake/reservoir/pond) culture of fast growing compatible species of different feeding habits and ecological niches is being practiced in different parts of the globe. This is popularly known as composite fish culture or mixed farming. Term polyculture is also loosely applicable for such a culture. In composite fish culture, all available food supply of the pond (phytoplankton, zooplankton, periphyton, macrophytes, benthos and detritus matter etc.) is most efficiently utilized by the cultured fishes. Such fishes do not harm each other; rather, they promote growth of other fishes. By proper care and management fish production can be raised by 5-6 times more than usual production through polyculture. Polyculture is the practice of culturing more than one

APPLIED ZOOLOGY AND LAB WORK

species of aquatic organism in the same pond. The motivating principle is that fish production in ponds may be maximized by raising a combination of species having different food habits. The concept of polyculture of fish is based on the concept of total utilization of different trophic and spatial niches of a pond in order to obtain maximum fish production per unit area. The mixture of fish gives better utilization of available natural food produced in a pond. The compatible fish species having complimentary feeding habits are stocked so that all the ecological niches of pond ecosystem are effectively utilised

Ponds that have been enriched through chemical fertilization, manuring or feeding practices contain abundant natural fish food organisms living at different depths and locations in the water column. Most fish feed predominantly on selected groups of these organisms. Polyculture should combine fish having different feeding habits in proportions that effectively utilize these natural foods. As a result, higher yields are obtained

Sewage fed fisheries is a new venture for India. Fish culture in sewage system involves little investment with higher yield. A sewage fed pond does not require fertilizers and supplemented food. This reduces the cost of culture and at the same time the growth rate of fish in such ponds is also faster. Unfortunately, in India the practice of sewage culture of fish is not very popular

10.8 TERMINAL QUESTIONS AND ANSWERS

- Q. 1 - What is Cold water aquaculture? Explain.
- Q. 2 - Write the scope of Cold water aquaculture in Uttarakhand.
- Q. 3 - Explain Scope of aquaculture for sustainable livelihood.
- Q. 4 - Explain Aquaculture of cold water fishes.
- Q. 5 - Describe in detail about Polyculture of carps.
- Q. 6 - Explain Sewage feed fisheries in detail.

1.1 OBJECTIVES

The study of Specimens, pictures and slides of the economically important animals. Study also includes permanent slides of Protozoans with particular reference to Entamoeba histolytica, Trypanosoma, Leishmania, Giardia, etc.

1.2 INTRODUCTION

Eversince, the beginning of civilization, man has been trying to make use of animals around him for the various purposes and to rear them for increasing their number. If we talk about bees, the first thing that comes to mind might be the picture of a well-structured colony of insects flying around a honeycomb made of perfectly constructed wax cells full of honey. But the truth is that not all bees known nowadays live in hierarchical communities and make honey. Actually, most species of bees develop into a solitary life-form unlike the classical and well-known honey bees (which are so appreciated in Bee-keeping). Through this topic, we'll try to sum up the different life-forms of bees in order to shed light on this chapter. In this topic, we will get introduced with the major aspects of apiculture (Bee-keeping), lac-culture (rearing lac insects) and sericulture (rearing silk moths) and also we will study the specimens, pictures and slide of the parasitic animal.

1.2 STUDY OF SPECIMENS/SLIDES

A **zoological specimen** is an animal or part of an animal which are preserved for scientific use and various uses are i.e. to verify the identification of a [species](#) and allow for the study of the concern animal and increase public knowledge of [zoology](#). Zoological specimens are extremely diverse. Examples, the study of the skin of bird and

mammal, [mounted specimens](#), skeletal material, casts, pinned insects, dried material, whole animals preserved in spirit and microscopic slides. [Natural history museums](#) are repositories of zoological specimens.

1.2.1 SPECIMENS STUDY OF APIS

Scientific Classification of Apis

Kingdom: Animalia

Phylum	Arthropoda
Class	Insecta
Sub-Class	Prerygota
Order	Hymenoptera
Genus	<i>Apis</i>
Species	<i>A.cerana</i>
Sub-species	<i>A.c.indica</i>
Trinomial Name:	<i>Apis ceranaindica</i>

Apis ceranaindica, the Indian honey bee, is a subspecies of [Asiatic honey bee](#). It is one of the predominant bees found and domesticated in India, Pakistan, Nepal, Burma, Bangladesh, Sri Lanka, Thailand and mainland Asia. Relatively non-aggressive and rarely exhibiting [swarming behavior](#), it is ideal for beekeeping. It is similar to the [European honey bee](#) (*Apis mellifera*), which tends to be slightly larger and can be readily distinguished. They usually build multiple combed nests in tree hollows and man-made structures. These bees can adapt to living in purpose-made hives and cavities. Their nesting habit means that they can potentially colonize temperate or mountain areas with prolonged winters or cold temperatures.

APPLIED ZOOLOGY AND LAB WORK

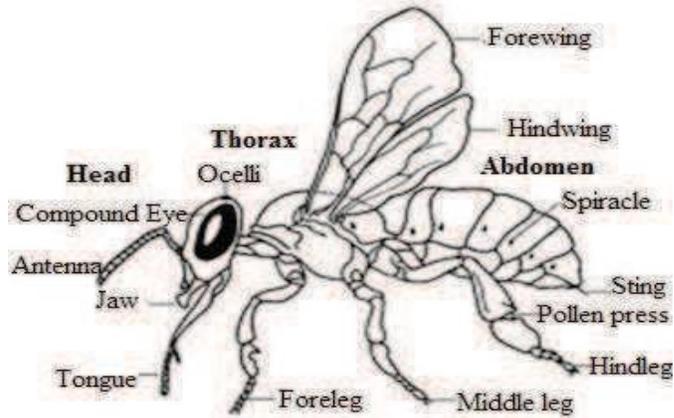

Fig. 1.1 Anatomy of Honey bee

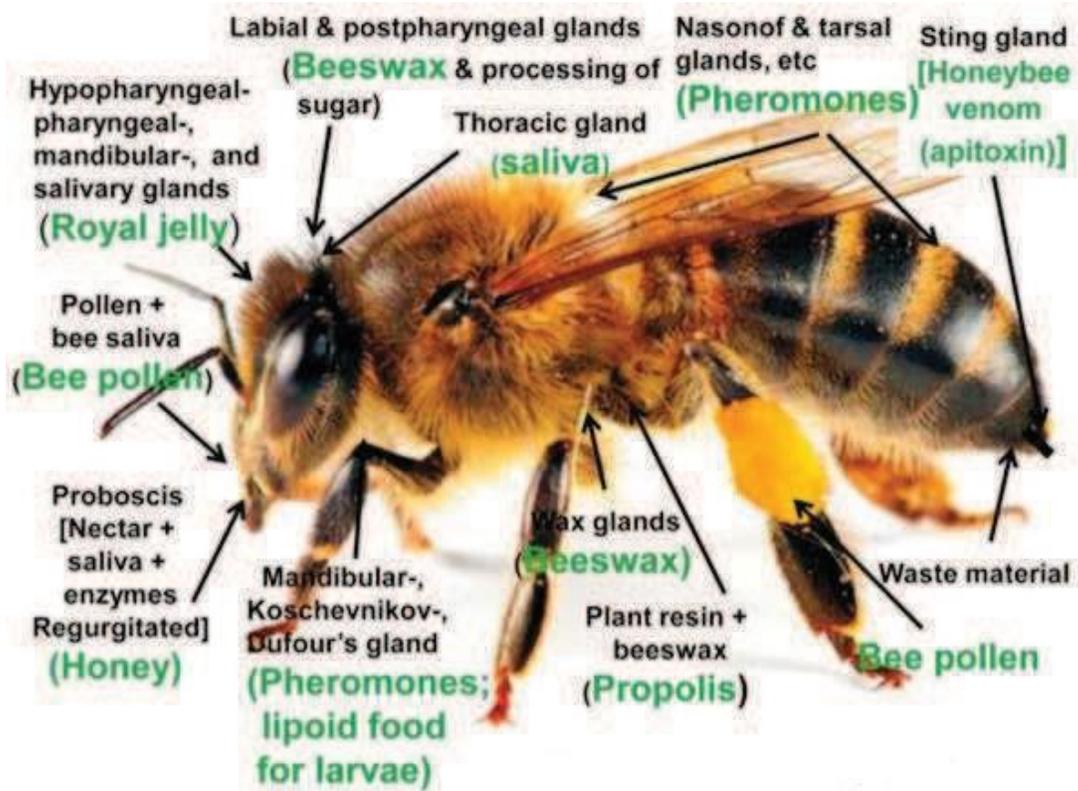

Fig.1.2 Honey bee (*Apis mellifera*)

Fig 1.3 (A) Life history of Honey bee (Isolated Stages)

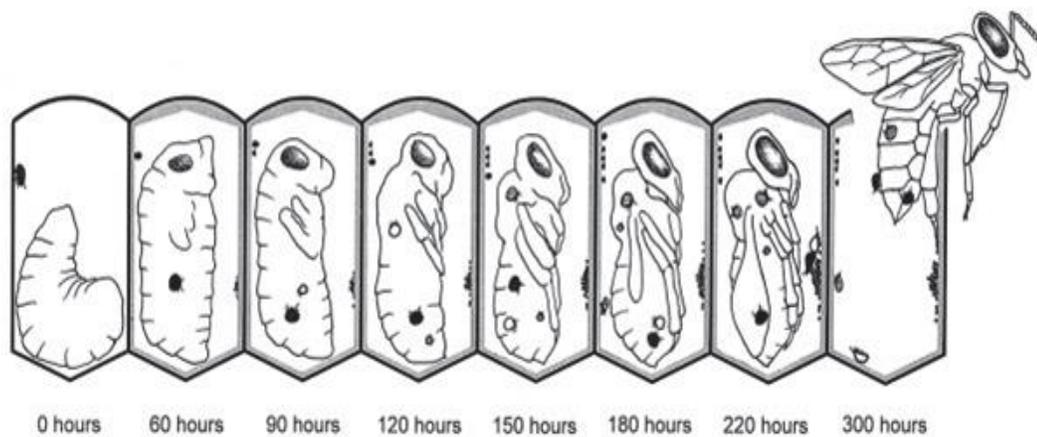

Fig.1.3 (B) Life history of Honey bee(Inside the comb cells)

Common varieties of bees:-

Common species of honey bees that commonly reared are *Apis dorsata* (rock bee), *Apis indica* (Indian bee), *Apis florea* (little bee) and *Apis mellifera* (Italian bee). Note that bee keepers mostly take care of only species whose names start with "Apis"- that is because only these species produce honey.

APPLIED ZOOLOGY AND LAB WORK

- ***Apis dorsata***: It is a giant bee and yields about 37 kg of honey per colony.
- ***Apis indica***: It can be easily domesticated and is most commonly used for honey production. The annual yield of honey is 2 to 5 kg per colony.
- ***Apis florea***: It rarely stings and thus honey extraction from its hive is easy. It produces about 1 kg of honey per colony per year.
- ***Apis mellifera***: This species has a very typical dance routine to indicate food availability, and like the little bee, stingless. As the common name suggests, this species is not local. However, because of the high amount of honey produced, it is often reared by bee keepers.

1.2.2 SPECIMENS STUDY OF SILK MOTH

Bombyx mori is commonly called as the Mulberry silk moth or Chinese silkworm. The silkworm is the larva or caterpillar or imago of the domestic silkworm, *Bombyx mori*. It is an economically important insect, being a primary producer of silk.

Systematic Position of *Bombyx mori*:-

Kingdom	Animalia
Phylum	Arthropoda
Class	Insecta
Sub – Class	Pterygota
Order	Lepidoptera
Family	Bombycidae
Genus	<i>Bombyx</i>
Species	<i>mori</i>

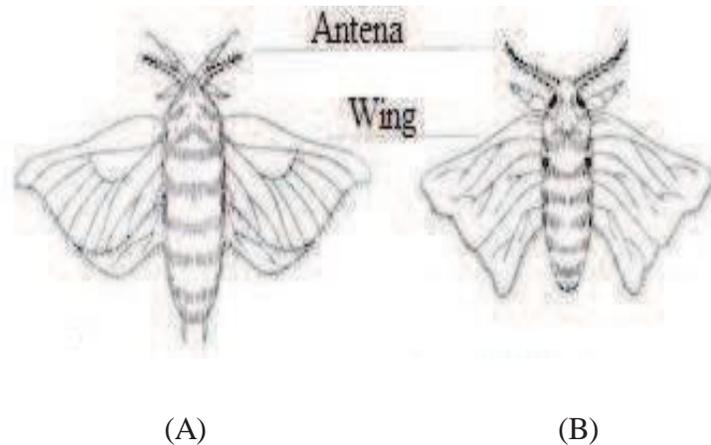

Fig 1.4 *Bombyx mori* mulberry feeding silkworm (A) Female (B) Male

Habit, Habitat and External feature of the Silkworm:-

Bombyx mori or mulberry worm is fully domesticated animal. The adult moth is primarily concerned with the reproduction. The larva (silk worm) of the silk moth is gluttonous voracious eater, and they feed on the leaf of the mulberry tree. Some silkworms are univoltine (Univoltine are also known as **Univoltine**) and some are multivoltine (Multivoltine are also known as **Multivoltine**). The adult moth is about 25mm long. The female silkworm is larger than the male. The moth is quite robust and creamy-white in colour and the body is distinctly divisible into three regions, namely as Head, thorax and abdomen, the head bears a pair of eyes, a pair of feathery antennae and the mouthparts. The thorax region bears three pairs of legs and two pairs of wings and the entire body is covered by minute scales.

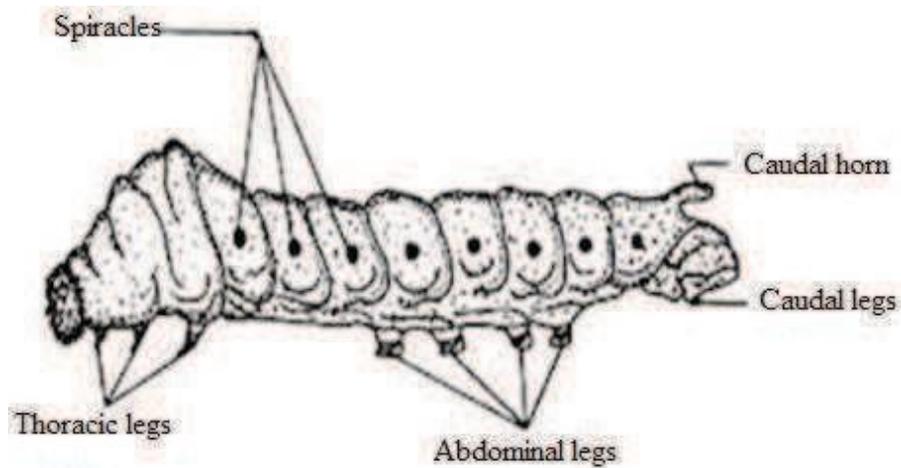

Fig.1.5 Bombyx mori.5thinstar larva, Lateral view

Silk:-

The pupa secrete a covering around its body and enclosed in it. This is know as cocoon. Thuspupa lives inside cocoon. The formulation of cocoon is called as spinning.

The cocoon is made of one thread of raw silk from 300 to 900 meters (1000 to 3000 feet) long. The silken fibers are very thin. About 2,000 to 5,000 cocoons are needed to make a pound of silk. If the animal is allowed to survive after spinning its cocoon; it makes a hole in the cocoon and exits as a moth. This stage cut the threads and ruin the silk. Instead, silkworm cocoons are thrown into boiling water, which kills the silkworms and also makes the cocoons easier to unravel. Often, the silkworm itself is eaten. The adult silkworms (moths) cannot fly. The silkworm-moths have wings about 2 inches wide and a white hairy body. Females and males are similarly in color. Adult silkworms have small mouths and do not eat.

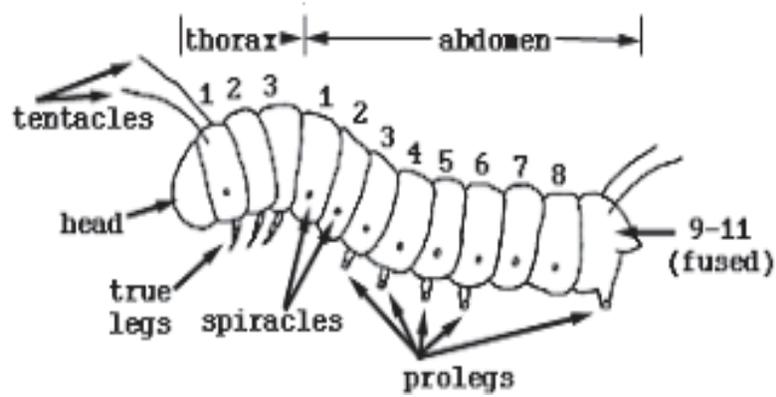

Fig.1.6 Caterpillar anatomy

Life history of the *Bombyx mori*:-

The silk moth is dioecious i.e.the sexes are separate. Fertilization is internal and preceded by copulation. The development includes a complicated metamorphosis.

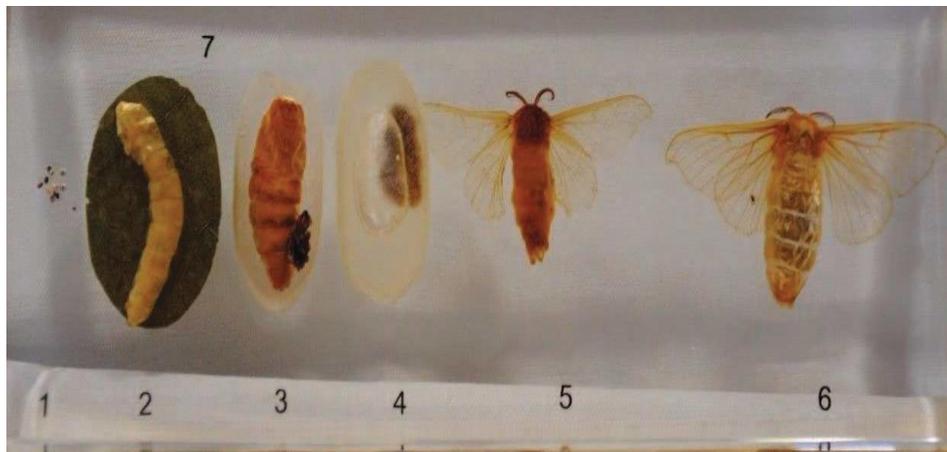

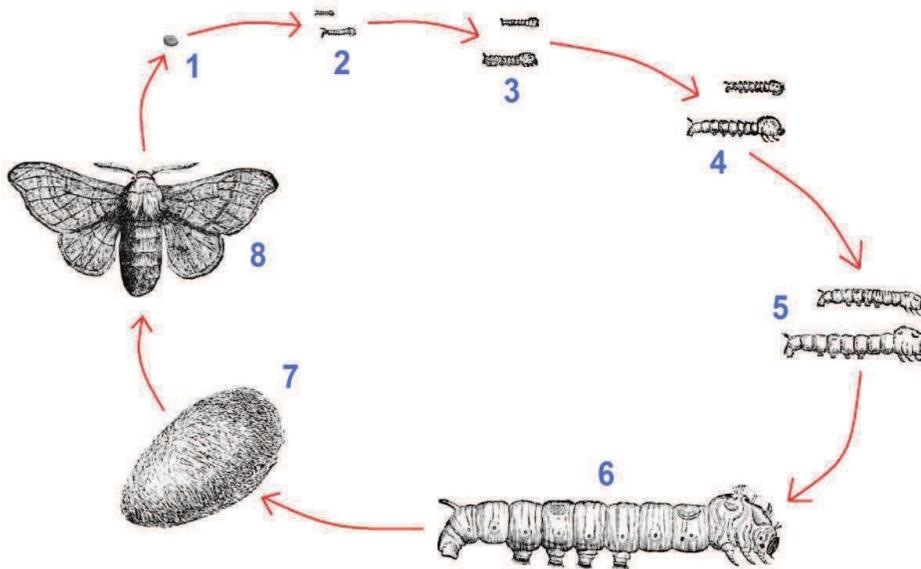

Fig.1.7 Representation of the life cycle of Silkworm in Museum specimen

APPLIED ZOOLOGY AND LAB WORK

Eggs:-

Female silkworm lays about 500 eggs at a time. She lays eggs on the leaves of mulberry trees. The eggs are covered with gelatinous secretion by which they stick to the leaves. Female moth (silk worm) lays eggs and dies after laying eggs as she does not eat anything. The eggs are kept in a cool place so that they can be stored for a long time. In a favourable condition, they hatch into larva. Larva is formed in about 2 weeks from eggs at a temperature of 18 to 25 degree celsius.

Life cycle of Bombyx mori (Showing, etamorphosis)

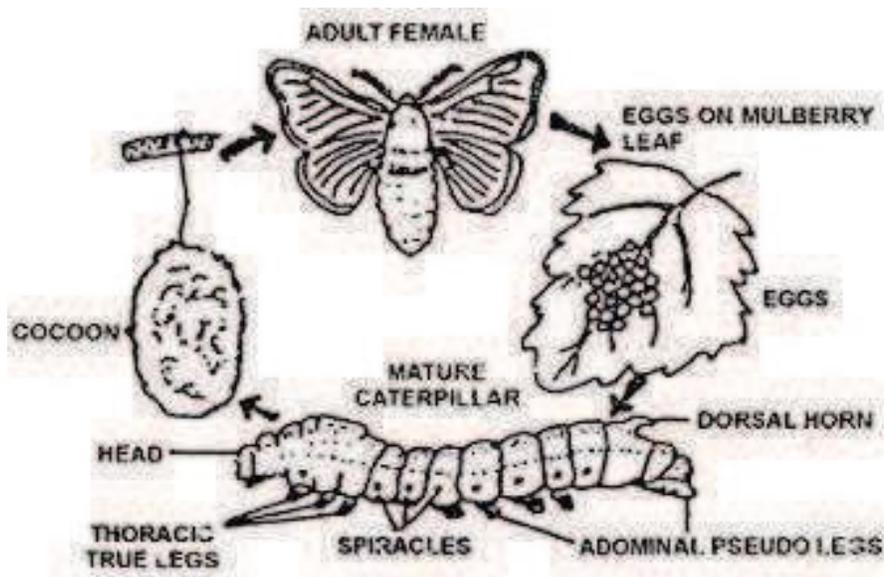

Fig.1.8 Life cycle of Silk moth

Silk Production:-

Silk is the natural protein fiber, some form of which can woven into textile. TheSilk cocoons is composed of primarily of three type of protein, which consist of the glue like glycoproteinsericin and heavyand light chains ofthe structural fibrous protein fibroin, It has been shown that fibroin resolubilized into an aqueous solution and then form into number of different of different geometrical form to produce regenerated silk. Derived silk is highly biocompatible within theand also demonstrated an impressive range of material properties based on variety of processing protocol. The best known type of silk is obtained from the cocoons of the larvae of the mulberry silkworm (*Bombyxmori*) reared in captivity of sericulture.

Economic Importance of Silk worm:-

A. In business:

1. Sericulture is a small scale, agro based cottage industry.
2. In India, the sericulture is carried out in about 27500 villages.
3. It provides self employment.

B. As source of Employment:

1. In different states of India more than 4 million people are employed in sericulture.
2. Thus, sericulture provides jobs and is a source of income.

C. Clothing:

1. Sericulture substitutes the cotton textile industry.
2. Fine delicate clothes are prepared from silk threads.
3. Silk threads are also exported. India gets large foreign exchange by silk exports.

D. Importance of silk:

There are many other uses of silk:

1. Silk is used in the preparation of garments.
2. Silk is used in the preparation of parachute cords.
3. It is used in Preparation of fishing line and elastic webs.
4. It is used in preparation of race tyres of cars and two wheelers.
5. It is used in insulation coils for telephone and wireless receivers.

1.2.3 SPECIMENS STUDY OF LAC INSECT

Lac is a natural resin. Other forms of all the resin are artificial. That is why it is called 'boon of nature, the insects of lakhs are very subtle and provide financial support by generating lakhs of their body. In scientific language lakhs are called **lasiferalakhha**. The word 'lakha' is derived from the Sanskrit word 'Laksh', possibly due to the number of infants (i.e. attention) infant insects from females. Worms of approximately 34 thousand million are equal to one kg Colorful lacquers and 14 thousand 4 hundred million insects', one kg Kusumi lakhs produce.

Systematic Position:-

APPLIED ZOOLOGY AND LAB WORK

Phylum	Athropoda
Class	Insecta
Sub-Class	Pterygota
Order	Hemiptera
Sub-Order	Homoptera
Family	Leciferidae
Genus	<i>Tachardia</i>
Species	<i>lacca</i>

Lac insect (*Tachardialacca*) previously known as laccifer lacca is a minute, resinous crawling scale insect which inserts its beak into plant tissue. Suck juices and grows and secretes lac from the hind end the body. Its own body ultimately gets covered with lac in the cell. The male insect (winged)is red in colour in appearance and around 1 to 1.5 mm in length it secretes bright creamylac where the female (wingless) are larger thanthe male and measure about 3 to 5 mmin length, the pyriform body of the female is enclosed in a resinous cell where the head, thorax and abdomen are not clearly distinct.

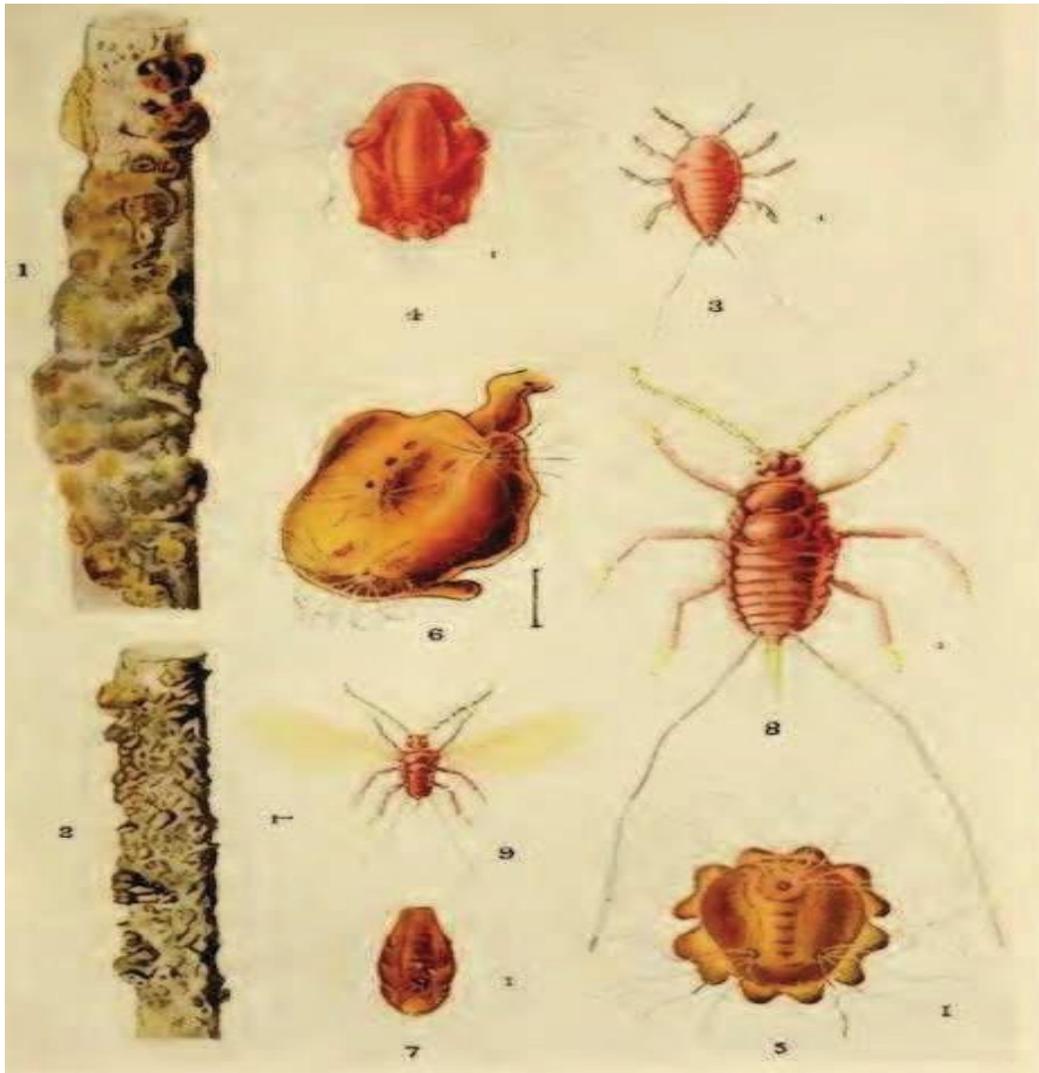

Fig.1.10 museum specimen of lac insect

LifeCycle of theTachar dialacca:-

It is a minute, crawling scale insect which sucks juices from plant twigs and secretes lac from its hind end of the body. Life cycle comprises of eggs, nymphs and adult male& female insects.

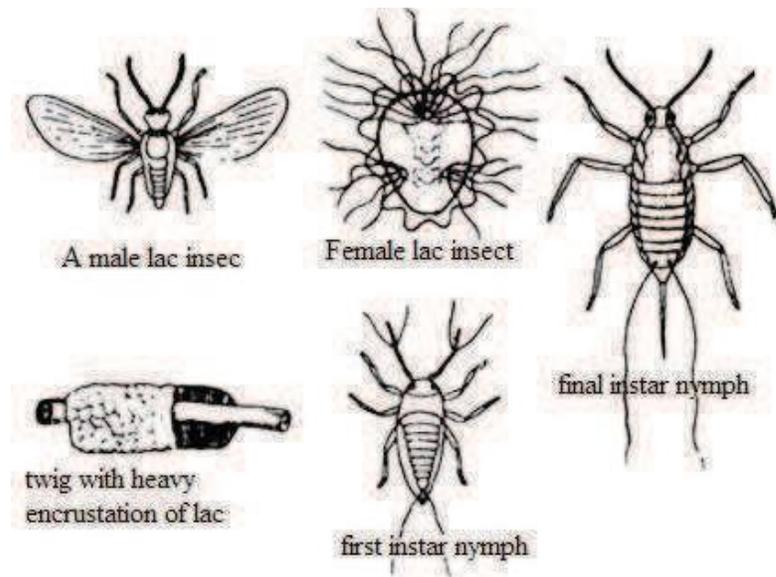

Fig.1.10 Life history of the *Tachardialacca*

After fertilization each mature female lays about 200-500 eggs in a cell of lac in which she is enclosed in the month of October & November. After six weeks of incubation, the eggs are hatched into first instar nymphs in the month of November and December. These nymphs emerges out as second instar nymphs in mass called 'swarms'. After sue to eight weeks nymphs metamorphosed into adults. The females get fixed on the host plant & secrets lac till it dies.

EconomicImportance:

Lac is a very important material used in making jewelry, paints, varnishes toys, buttons, and photographic material, insulating material for electric goods, ship industry, and office furniture sealing wax and in other things. India produces about 50-60 percent of the total lac output in the world.

1.3 MAJORCARPS

Indian Major Carps (IMC)

Indian carp or **Indian major carp** is a common name for several species of fish and commonly may refer to the following species now raised in aquaculture in South Asia and other Asian countries where they have been introduced.

- [Labeo rohita](#), the rohu is an Indian major carp, a fish of the carp family found in rivers in South Asia.
- [Catla catla](#), or **catla**, is an Indian major carp. It is an economically important South Asian freshwater fish of the carp family.
- [Cirrhinus cirrhosus](#), or **mrigal**, is an Indian major carp, a ray-finned fish of the carp family native to rivers in India.
- There are some exotic carps such as grass carp, common carp and silver carp.

Rohu (Labeo rohita)

Systematic Position:-

Phylum:	Chordata
SuperClass	Pisces
Class:	Actinopterygii
Sub-Class	Actinopteryos
Order	Cypriniformes
Family:	Cyprinidae
Genus:	Labeo

APPLIED ZOOLOGY AND LAB WORK

Species: *rohita*

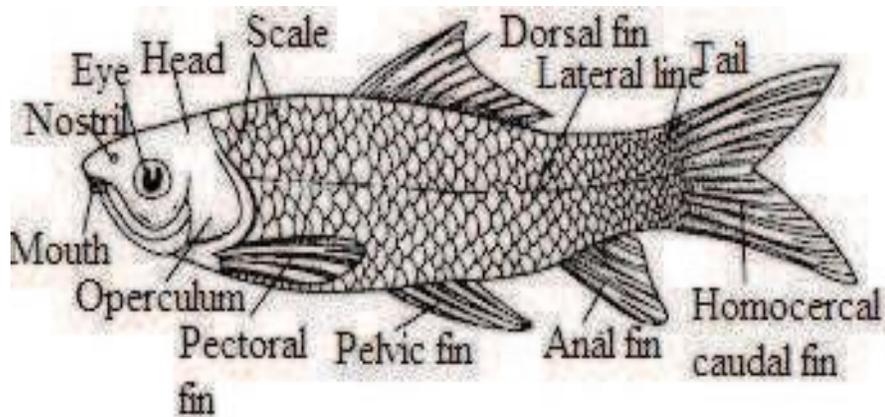

Fig.1.11 Labeo rohita

1. It is a medium sized carp and attains a length of 60cm.
2. It is widely distributed in India and is often cultured with other major carps.
3. The species is an omnivore with specific food preferences at different life stages
4. It eats mainly [zooplankton](#), but as it grows, it eats more and more [phytoplankton](#), and as a juvenile or adult is a herbivorous column feeder.
5. Rohu reaches sexual maturity between two and five years of age. They generally spawn during the [monsoon](#) season
6. The rohu is an important [aquacultured](#) fresh water species in South Asia. When cultured, it does not breed in [lake ecosystems](#), so induced spawning is necessary

APPLIED ZOOLOGY AND LAB WORK

Catla (*Catla catla*)

Systematic Position:-

Phylum: [Chordate](#)

Class: [Actinopterygii](#)

Superclass Pisces

Genus Catla

Family: [Cyprinidae](#)

Species: *G.catla*

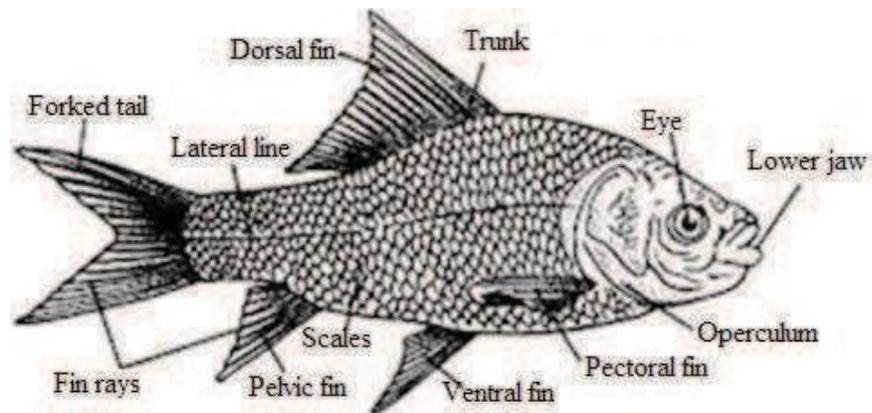

Fig.1.12 *Catlacatla*

1. It is largest Indian Car and commonly known as Catla.
2. Body is elongated broad and stout measuring more than meter length.
3. Colour is brackish grey or above and silvery on the sides.

APPLIED ZOOLOGY AND LAB WORK

4. Scales are pink or coppery in the center on the dorsal side and whitish below.
5. Dorsal profile of the body is more convex.
6. It is a surface feeder, which feeds the small crustacean, insects, rotifers, algae, etc.
7. It takes two years to get fully mature, it breeds during the month of May to September and lays an egg rate of 80,000 to 1,50,000 per kg body weight.
8. This fish is mainly found in India, Pakistan, Bangladesh, Myanmar and Sri Lanka, etc.

Mrigal carp (*Cirrhinus mrigala*)

Systemati

c

Position:

Phylum:

[Chordata](#)

Class: [Actinopterygii](#)

SuperClass: Pisces

Genus: [Cirrhinus](#)

Species: *C. cirrhosus*

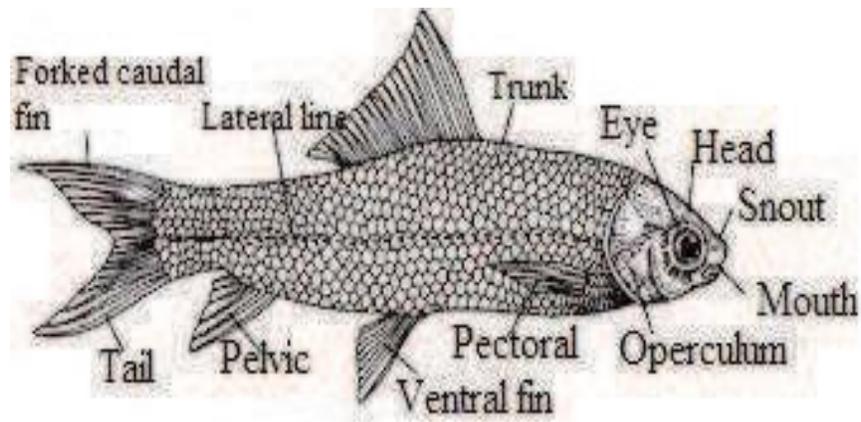

Fig.1.13 *Cirrhinus mrigala*

1. The **mrigal carp** (*Cirrhinus cirrhosus*, also *Cirrhinus mrigala*, also known as the **mrigal** and the **white carp**).
2. It is a species of [ray-finned fish](#) in the [carp family](#).
3. It is native to streams and rivers in India and the only surviving wild population is in the [Cauvery River](#).
4. It is widely [aquafarmed](#) and [introduced](#) populations exist outside its native range. It reaches a maximum length of 1 m (3.3 ft).
5. Mrigal is the benthopelagic and potamodromous plankton feeder.
6. It inhabits fast-flowing streams and rivers, but cannot tolerate high levels of salinity.
7. Spawning occurs in marginal areas of the water bodies with a depth of 50 to 100 centimeters.

Exotic Carps

Grass Carp (*Ctenopharyngodon idella*)

1. Grass carp is mainly herbivorous but juveniles are omnivorous.
2. Spawns on river beds with very strong current.

APPLIED ZOOLOGY AND LAB WORK

3. They can tolerate a wider range of temperature.
4. Occur in lake, pond, pools and rivers etc.

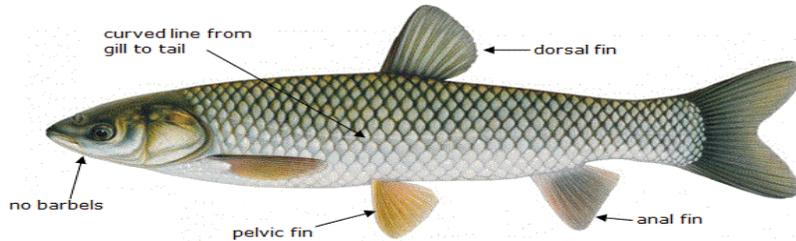

Fig.1.14 Grass carp (*Ctenopharyngodonidella*)

Common carp (*Cyprinus carpio*)

1. This is known as European carp.
2. Olive green coloration above and yellowish below.
3. Generally fine and fins are often reddish.
4. Body laterally compressed.
5. Body height 1/4 of body length.
6. Triangular head with blunt snout and thick nose plate.

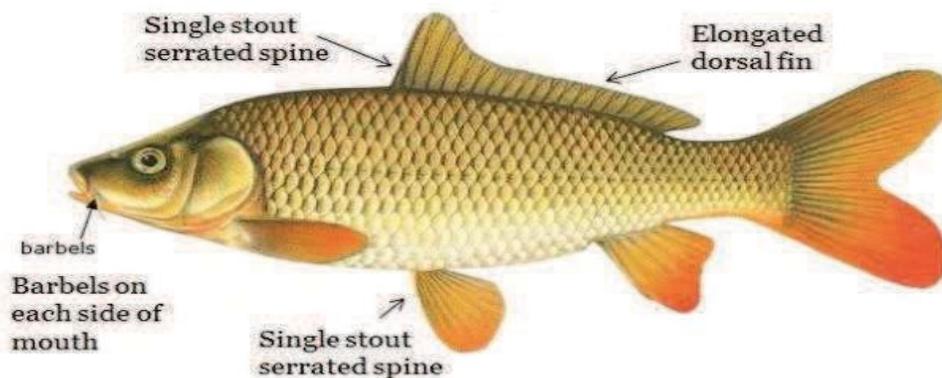

Fig.1.15 Common carp (*Cyprinus carpio*)

APPLIED ZOOLOGY AND LAB WORK

Silver carp (*Hypophthalmichthys molitrix*):-

1. The silver carp (*Hypophthalmichthys molitrix*) is a species of [freshwater cyprinid fish](#),
2. a variety of [Asian carp](#) native to China and eastern [Siberia](#). Although a [threatened species](#) in its natural habitat.
3. It has long been cultivated in China. By weight more silver carp are reproduced worldwide in [aquaculture](#) than any other species of fish except for the [grass carp](#).
4. Silver carp are usually farmed in polyculture with other [Asian carp](#), or sometimes with [catla](#) or other fish species.
5. This species has also been [introduced](#) to, or spread by connected waterways, into at least 88 countries around the world.
6. The reason for its importance was' generally for use in aquaculture, but enhancement of [wild fisheries](#) and water quality control have also been intended on occasion. In some of these places the species is considered an [invasive species](#)

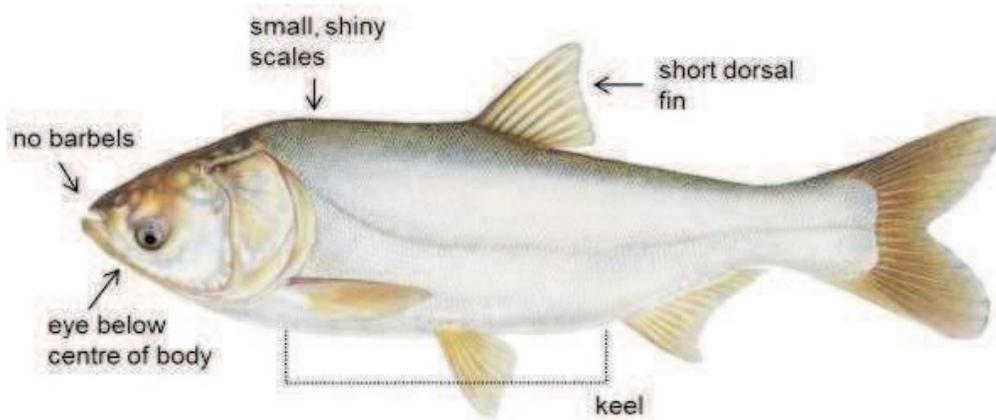

Fig.1.16 Silver carp (*Hypophthalmichthys molitrix*)

1.4 STORED GRAIN PEST CAPS

APPLIED ZOOLOGY AND LAB WORK

In Montana, almost all stored-grain insects are beetles and weevils in the **Order Coleoptera**. There are occurrences of moths pests (**Lepidoptera**). Members of seven other insect Orders are also found in grain storage throughout the world, but the major pests are still primarily from the **Coleoptera** and the **Lepidoptera**.

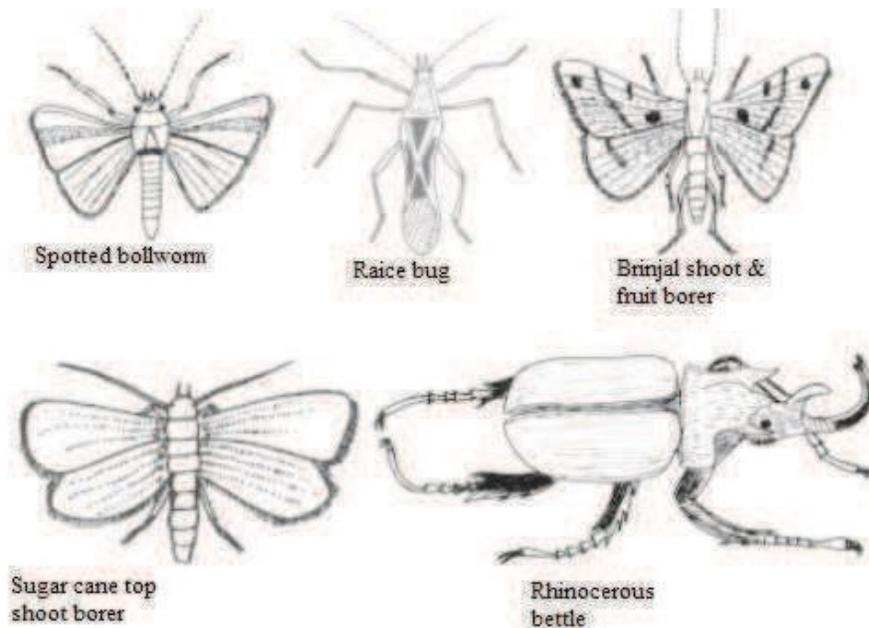

Fig.1.17 Common pests of crops

Some common Stored Grain Pest's

1. **Pulse beetle** (*Callosobruchus maculatus*): It is a species of beetle commonly known as cowpea weevil or cowpea red beetle. It is a member of the leaf beetles family Chrysomelidae hence not a true weevil.

APPLIED ZOOLOGY AND LAB WORK

Systematic Position: Kingdom

Animalia

Phylum- Arthropoda

Class- Insecta

SubClass- Pterygota

Order- Coleoptera

Family- Chrysomelidae

Genus-

Callosobruchus

Species-
maculatus

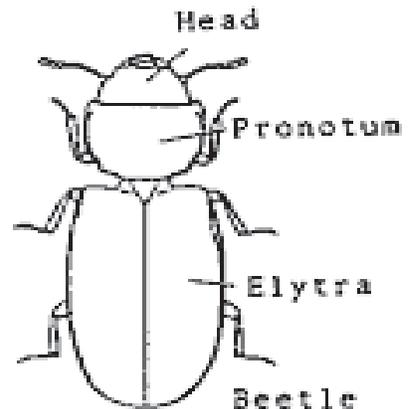

Fig.1.17 *Callosobruchus maculatus*

2. Rice-Weevil (*Sitophilus oryzae*): The rice weevil is a stored product pest of not only rice but almost of all cereals & their products. It is called as rice weevil because its breeding habits & life-cycle was first of all studied in rice.

Systematic Position: Kingdom

Animalia

Phylum- Arthropoda

Class- Insecta

SubClass- Pterygota

Order- Coleoptera

Family- Curculionidae

Genus- *Sitophilus*

Species-
oryzae

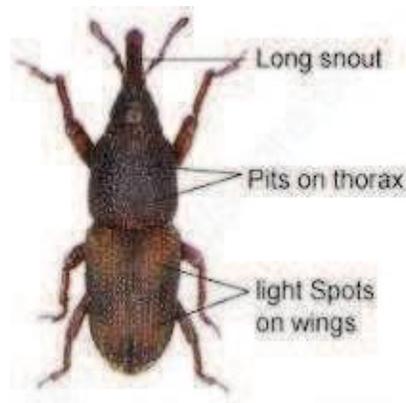

Fig.1.18 *Sitophilus oryzae*

APPLIED ZOOLOGY AND LAB WORK

3. Wheat Weevil (*Trogoderma granarium*): The pest is cosmopolitan in distribution; it is also called a cabinet beetle. It initially originated in South Asia, wheat weevil is regarded as the most destructive pest of the grain products & seeds.

Systematic Position:

Kingdom – Animalia

Phylum– Arthropoda

Class– Insecta

SubClass - Pterygota

Order– Coleoptera

Family– Dermestidae

Genus *Trogoderma*

Species– *granarium*

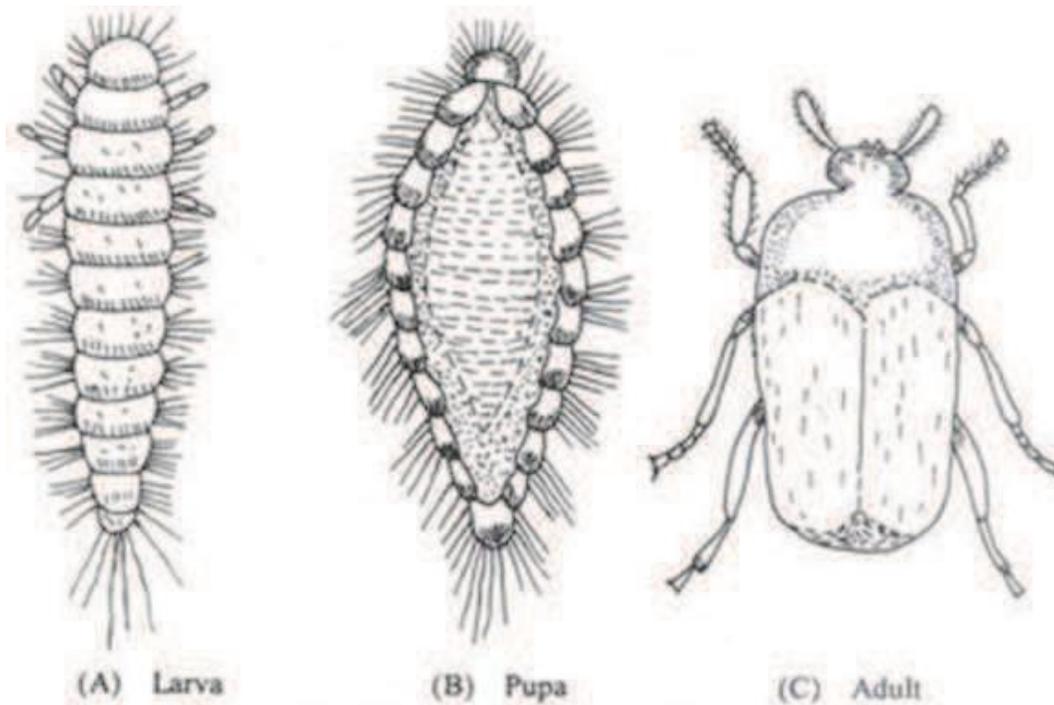

Fig.1.18 *Trogoderma granarium*

4. Rustred flour beetle (*Tribolium castaneum*): The weevil is commonly called a rusted flour beetle. It is cosmopolitan in nature. It initially originated in the Indian Subcontinent but now found throughout all tropical, subtropical and warm temperate regions of the world.

Systematic Position:

Kingdom – Animalia

Phylum-Arthropoda

Class– Insecta

SubClass - Petrygota

Order– Coleoptera

Family–Tenebrionidae

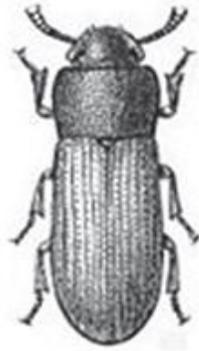

Fig.1.19 *Tribolium castaneum*

It is a worldwide serious pest of stored products particularly food grains like flour, cereals, pasta, biscuits, nuts, oil cakes, dried fruits, meal beans, dried pet food, dried flowers, chocolate, seeds, and even dried museum specimens. This beetle is the most important pest of stored products inside the home, food industry & grocery stores. It is different from the confused floor beetle (*Tribolium confusum*) by having different antennae shape & its ability to fly under stressed conditions.

1.5 PICTURE OF ECONOMICALLY IMPORTANT VARIETIES OF POULTRY

Today India is the world's fifth largest egg producer and the eighteenth largest producer of broilers and its per capita consumption of such products is poor - 37 eggs and 1 kg of poultry meat per capita per annum. The growth of the Poultry Industry in India is marked by an increase in the size of the poultry farm. Extra income is obtained from [poultry](#) farming at small levels in rural areas and simultaneous use of poultry (feces) is used to make [compost](#) for button mushroom production and manure use in kharo as fertilizer increases the productivity of the crop. Use advanced breed seeds, courageous,

APPLIED ZOOLOGY AND LAB WORK

beneficial, and beneficial developed from [centralbird research institute](#), Izzatnagar Bareilly in rural areas. The expense incurred in this adherence to compensate is by selling the poultry in the fifth month. After that, egg production yields good earnings for 12-15 months from the hen. More vermicomposts received during the preparation of Vermicompost receive more production than giving food to poultry. Similarly, the peacock is also used by poultry. Nearly 40 chickens have the same nutrient content as feces, as they are obtained from a [cowdung](#). Fowls are widely distributed as domesticated animals since times

immemorial. In twentieth century poultry keeping has become an important small scale industry due to modern need for palatable and nutritive food which it provides in the form of eggs as well as adult animals. The storage and transport facilities also have helped to a great extent in its becoming popular as a trade. This naturally has attracted the attention of the people at large and the scientists in particular necessitating new researches on breeding, hatching and rearing of fowls. India is the native place of the wild jungle fowl but little attention has been paid for developing poultry industry in comparison to other countries. In country like India, the increased egg consumption is essential for the proper nutrition of human beings. The researches carried out at the Imperial Veterinary Research Institute, Izzatnagar have demonstrated the high biological value of eggs and recommended the consumption of eggs in supplementing the defective human diets. For the successful management of poultry industry one should have detailed idea about the poultry ground, habitat of fowl, breeds, breeding and rearing of chickens. Though there are several Government Poultry Farms in India but the poultry is almost entirely in the hands of poor persons, thus eggs available are of small size.

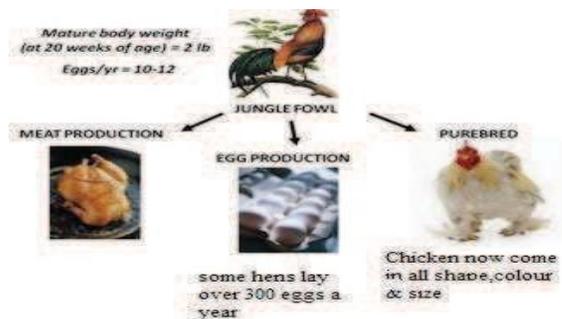

Fig1.20 Habitat of Fowl

1. Soil. For fowls, soil should be sandy, gravelly and abounding in kunkar alongwith good amount of lime. The stony soil is not suitable for fowls because stones cause damage to feet of the fowl. The heavy soil with high percentage of moisture is harmful. The marshy, dirty and drained grounds are fatal to the animals.

2. Shelter. The poultry should be protected from the cold winds and heavy rains. They should not be allowed to walk in water.

3. Shade. The poultry should be well protected from hot sun and hot wind in summer season, so the site for the poultry ground should be such as to have a number of shrubs and trees. In summer season the west side of the poultry house should be closed in the daytime otherwise they will die due to westerly wind. The places where trees are not found, a shed of 10 to 15 square feet should be made with bamboo and straw. The shed should be kept 3 feet above the ground surface with the help of bamboo posts. The ground where such shades are not possible, it may be constructed with metal and raised 2 feet from the ground on stone pillars. The ground beneath the shed should be raised about 3 inches from general surface for good drainage.

1.5.1 PARASITES/SLIDE STUDY

1.5.1.1 Parasites/Slide study of Trypanosomes & E. histolytica

Systematic position:

Phylum: Protozoa

Subphylum: Sarcodina

Super class: Mastigophora

APPLIED ZOOLOGY AND LAB WORK

Class: Zoomastigophora

Order: Kinetoplastida

Genus: *Trypanosoma*

Species: *gambianse*

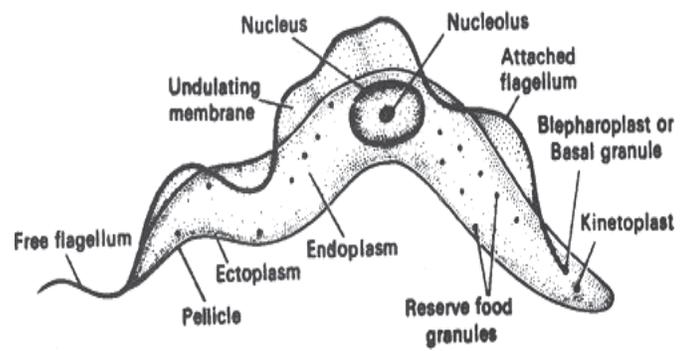

Fig.1.21 *Trypanosoma*

APPLIED ZOOLOGY AND LAB WORK

Distribution:-

It is found in Africa and America. It has been reported from India also.

Comments

- Unicellular, microscopic, simple animal commonly found in Africa.
- It is an endoparasite found in blood and other tissues of man and other vertebrates. It causes Trypanosomiasis or Sleeping sickness.
- It is digenetic i.e. it completes its life cycle in two hosts: principal host in man and intermediate host is a blood sucking insect *Glossina palpalis* or Tsetse fly.
- It is a polymorphic species exists in man and a trichinidial form in tsetse fly
- A single flagellum arises from a basal body placed near the posterior end
- Reproduction takes place by longitudinal binary fission

Host:

It is an endoparasite in blood and tissues of man and other vertebrates like Pig, Buffaloes and antelopes etc; which are its reservoir hosts.

Symptoms of the Disease:

Several species of trypanosomes are known. *T. cruzi* causes Chagas disease, *T. brucei* causes Nagana disease but *T. gambiense* and *T. rhodesiense* causing sleeping sickness are by far the most important and well known among the trypanosome species. The parasite invades the cerebrospinal fluid resulting in a recurrent fever. The patient becomes weak, anemic and loses weight. Strong tendency to fall asleep is observed in the initial stages and can

APPLIED ZOOLOGY AND LAB WORK
lead to coma and death if untreated.

ENTAMOEBAHISTOLYTICA

CLASSIFICATION

Phylum protozoa

Sub phylum

Sarcomastigophora

Class Rhizopoda

Order Lobosa

Genus *Entamoeba*

Species *histolytica*

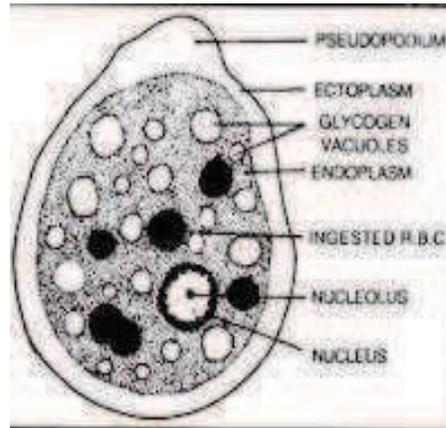

Fig.1.22 Entamoebahistolytica

APPLIED ZOOLOGY AND LAB WORK

Distribution:-

Entamoebahistolytica is worldwide in distribution, but its prevalence is greater in tropics and subtropics than in the temperate zones. It has been reported that incidence of infection is high in Mexico, China, India and parts of South America.

HabitsandHabitat:-

Entamoebahistolytica is a microscopic endoparasite of man .it is commonly found in the upper part of the large intestine and is very often lodged in the liver, lungs, brain and testes.

Comment:-

- *Entamoebahistolytica* is a small microscopic parasitic *Amoeba*. In its life cycle, it occurs in three distinct forms.
- Trophozoite or magna form.
- Precystic or minuta form.
- Cystic forms.

1.5.1.2 Parasites/Slide study of Leishmania & Giardia

Classification:-

Phylum: Protozoa

Subphylum: Sarcomastigophora

Class: Zoomastigophorea

APPLIED ZOOLOGY AND LAB WORK

Order: Kinetoplastida

Family: Trypanosomatidae

Genus: *Leishmania*

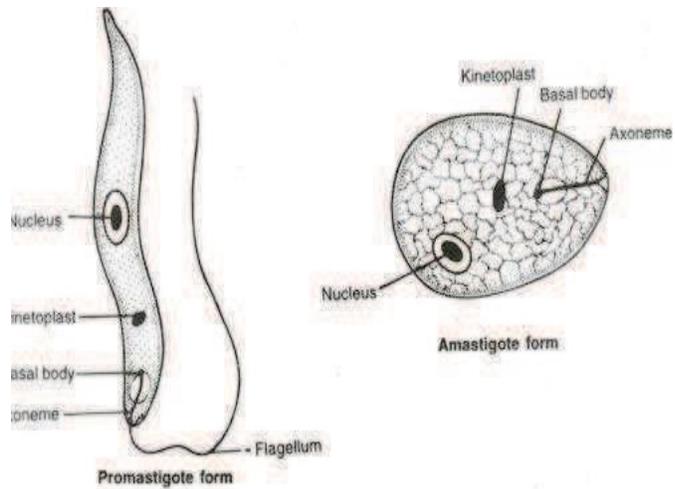

Fig.1.23Leishmania

APPLIED ZOOLOGY AND LAB WORK

Distribution:-

It is found as an intracellular parasite in Leucocytes and cells of liver, spleen, bone marrow, etc.

Morphology and Life Cycle:-

- *Leishmania* spp. are digenetic or heteroxenous parasites, whose life cycle involves two
- Hosts, a vertebrate and an invertebrate, the sandfly
- Hemoflagellates may have several morphological stages that differ from one another in the placement of the kinetoplast relative to the nucleus, as well as the location and origin of the flagellum³
- In *Leishmania* the life cycle stage in the vertebrate is the amastigote and in the insect, the promastigote. *Leishmania* exist in two basic body forms
 - (a) The amastigote, the intracellular form in the vertebrate host, and
 - (b) promastigote, the extracellular form in the sandfly (*Phlebotomus* spp. and *Lutzomyia* spp.) Vector
- Amastigotes are taken up from the blood of an infected host when the female sandfly bites, and in the sandfly gut they develop into promastigotes where they multiply by binary fission; promastigotes move anteriorly into the proboscis, and are introduced into the vertebrate host when the sandfly bites again. ⁵
- The promastigotes injected by the sandfly during feeding are phagocytized and develop into intracellular amastigotes.
- The amastigote, literally “without a flagellum,” is the intracellular, non-motile form in the vertebrate host, and it divides by longitudinal binary fission at 37°C. Intracellular amastigotes are 3-6 μm in length and 1.5-3.0 μm in width. ⁷
- The amastigote is also called the Leishman-Donovan (LD) body. The amastigote is not really devoid of a flagellum, it is simply that the flagellum does not protrude beyond the body surface and by light microscopy cannot be seen.

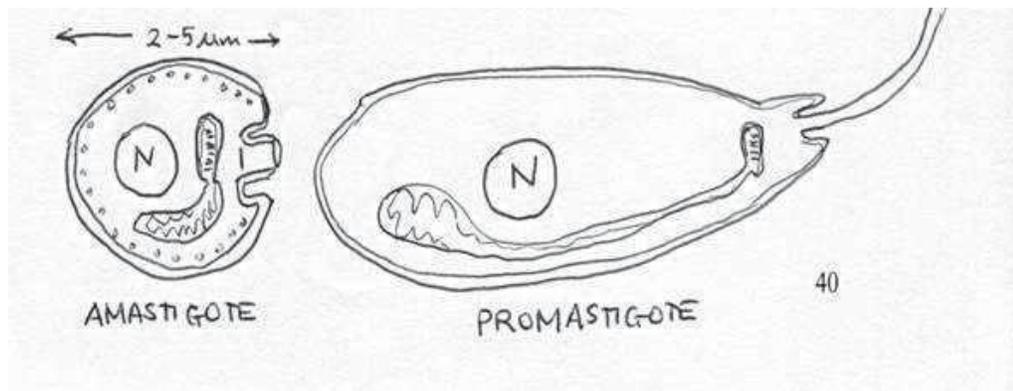

Fig.1.24 different stage of Leishmania

- The promastigote, literally the body form with "an anterior flagellum" is 15-30 μ m in body length and 5 μ m in width.
- it is extracellular, motile, and grows and divides by longitudinal binary fission at 27°C in the sand.

- 1.5.1.2.1 Soon after entering the gut, the amastigotes get coated with peritrophic matrix, which is composed of chitin and protein complex. This protects the parasites from the digestive enzymes of the host.
- 1.5.1.2.2 The amastigotes travel as far as the abdominal midgut and first transform into a weakly motile "procyclic promastigotes" on the gut wall within 1–3 days.
- 1.5.1.2.3 The young promastigotes secrete a neuropeptide that stops peristalsis of the gut. The surface lipophosphoglycan (LPG) of the promastigote serves as an attachment to the gut epithelium. These factors prevent the expulsion of promastigotes during excretion of the insect.
- 1.5.1.2.4 During 4–7 days the peritrophic matrix is degraded by the activity of chitinases. This releases the more actively motile "nectomonad promastigotes" which migrate anteriorly until they reach the opening of the thoracic gut.
- 1.5.1.2.5 Another transformation takes place by which they turn into "leptomonad promastigotes". These are fully motile and capable of binary fission. Multiplication and migration towards thoracic midgut cause congestion of the pharynx and buccal cavity.
- 1.5.1.2.6 Here they secrete promastigote secretory gel (PSG), which is composed

dof soluble acid phosphatase and phosphoglycoprotein.

- 1.5.1.2.7 After 6–9 days the promastigotes become metacyclic. Some are also transformed into Non-replicating promastigotes, which also become metacyclic. The sandfly is able to regurgitate and eject the parasites from its proboscis with the help of PSG when it bites.

Giardia:-

Classification

Phylum	Protozoa
Class	Zoomastigophora
Order	Diplomonadida
Genus	<i>Giardia</i>

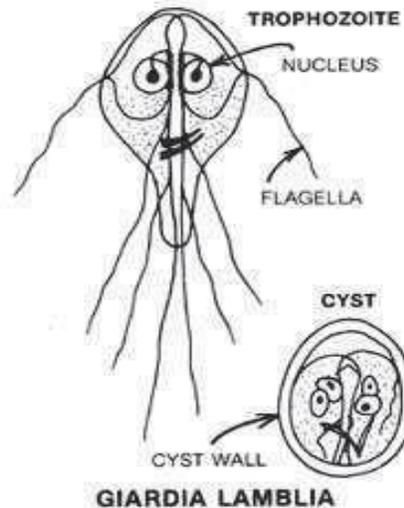

fig.1.25

Species Lamblia

Comments:-

- 1.5.1.2.7.1** It lives in the intestine of man as an endoparasite and causes **Giardiasis**
- 1.5.1.2.7.2 It has two nuclei and bears four flagella on either side of the body
- 1.5.1.2.7.3 It feeds on vitamins and amino acids contained in food within the intestine.
- 1.5.1.2.7.4 Giardia intestinalis trophozoites are pear-shaped and 10–20 μm long.
- 1.5.1.2.7.5 Other characteristics include: flagella, median bodies, sucking disks and two big nuclei. Giardia intestinalis cysts are oval to ellipsoid and 8–19 μm long
- 1.5.1.2.7.6 Immature cysts have two nuclei, whereas mature cysts have four.

Causal Agent:-

Giardia intestinalis a protozoan flagellate (Diplomonadida). This

protozoan was initially named *Cercomonas intestinalis* by Lambl in 1859. It was renamed *Giardia lamblia* by Stiles in 1915 in honor of Professor A. Giard of Paris and Dr. F. Lambl of Prague. However, many consider the name, *Giardia intestinalis*, to be the correct name for this protozoan. The International Commission on Zoological Nomenclature is reviewing this issue.

Life Cycle:-

Cysts are resistant forms and are responsible for transmission of giardiasis. Both cysts and trophozoites can be found in the feces (diagnostic stages)

- 1.5.1.2.7.7 The cysts are hardy and can survive several months in cold water. Infection occurs by the ingestion of cysts in contaminated water, food, or by the fecal-oral route (hands or fomites)
- 1.5.1.2.7.8 In the small intestine, excystation releases trophozoites (each cyst produces two trophozoites)
- 1.5.1.2.7.9 Trophozoites multiply by longitudinal binary fission, remaining in the lumen of the proximal small bowel where they can be free or attached to the mucosa by a ventral sucking disk.
- 1.5.1.2.7.10 Encystation occurs as the parasites transit toward the colon. The cyst is the stage found most commonly in non-diarrheal feces.
- 1.5.1.2.7.11 Because the cysts are infectious when passed in the stool or shortly afterward, person-to-person transmission is possible. While animals are infected with *Giardia lamblia*, their importance as a reservoir is unclear.
